Radiation Causes Genetic Damage

**Direct Effect**

Damage To DNA From Ionization

If radiation interacts with the atoms of the DNA molecule, or some other cellular component critical to the survival of the cell, it is referred to as a direct effect. Such an interaction may affect the ability of the cell to reproduce and, thus, survive. If enough atoms are affected such that the chromosomes do not replicate properly, or if there is significant alteration in the information carried by the DNA molecule, then the cell may be destroyed by "direct" interference with its life-sustaining system.

**Indirect Effect**

Radiolytic Decomposition of Water in a Cell

If a cell is exposed to radiation, the probability of the radiation interacting with the DNA molecule is very small since these critical components make up such a small part of the cell. However, each cell, just as is the case for the human body, is mostly water. Therefore, there is a much higher probability of radiation interacting with the water that makes up most of the cell's volume.

When radiation interacts with water, it may break the bonds that hold the water molecule together, producing fragments such as hydrogen (H) and hydroxyls (OH). These fragments may recombine or may interact with other fragments or ions to form compounds, such as water, which would not harm the cell. However, they could combine to form toxic substances, such as hydrogen peroxide (H₂O₂), which can contribute to the destruction of the cell.
Strong effects of ionizing radiation from Chernobyl on mutation rates

Anders Pape Møller¹ & Timothy A. Mousseau²

¹Laboratoire d’Ecologie, Systématique et Evolution, CNRS UMR 8079, Université Paris-Sud, Bâtiment 362, F-91405 Orsay Cedex, France, ²Department of Biological Sciences, University of South Carolina, Columbia SC 29208, USA.

In this paper we use a meta-analysis to examine the relationship between radiation and mutation rates in Chernobyl across 45 published studies, covering 30 species. Overall effect size of radiation on mutation rates estimated as Pearson’s product-moment correlation coefficient was very large ($E = 0.67$; 95% confidence intervals (CI) 0.59 to 0.73), accounting for 44.3% of the total variance in an unstructured random-effects model. Fail-safe calculations reflecting the number of unpublished null results needed to eliminate this average effect size showed the extreme robustness of this finding (Rosenberg’s method: 4135 at $p = 0.05$). Indirect tests did not provide any evidence of publication bias. The effect of radiation on mutations varied among taxa, with plants showing a larger effect than animals. Humans were shown to have intermediate sensitivity of mutations to radiation compared to other species. Effect size did not decrease over time, providing no evidence for an improvement in environmental conditions. The surprisingly high mean effect size suggests a strong impact of radioactive contamination on individual fitness in current and future generations, with potentially significant population-level consequences, even beyond the area contaminated with radioactive material.

Ionizing radiation, antioxidant response and oxidative damage: A meta-analysis

D. Eimor, A. Bonisoli-Alquati, D. Costantini, T.A. Mousseau, A.P. Møller

HIGHLIGHTS

- There is interest in variation in metabolic effects of chronic low-dose ionizing radiation
- A random effect meta-analysis of effect sizes of radioactive contamination was performed
- We found significant effects of radiation on oxidative damage and antioxidant response
- We found significant heterogeneity among biological matrices, species and age classes

GRAPHICAL ABSTRACT
Radiation, Genetic Damage, and Oxidative Stress Cause Many Effects on Development and Morphology

- Sperm morphology, swimming performance, and sterility
- Cataracts in eyes of birds and rodents
- Tumors in birds and rodents
- Brain size in birds and mammals
- Many other developmental malformations in birds, rodents, insects, plants
Aspermy, Sperm Quality and Radiation in Chernobyl Birds

Abstract

**Background:** Following the Chernobyl nuclear power plant accident, large amounts of radionuclides were emitted and spread in the environment. Animals living in such contaminated areas are predicted to suffer fitness costs including reductions in the quality and quantity of gametes.

**Methodology/Principal Findings:** We studied whether aspermy and sperm quality were affected by radioactive contamination by examining ejaculates from wild caught birds breeding in areas varying in background radiation level by more than three orders of magnitude around Chernobyl, Ukraine. The frequency of males with aspermy increased logarithmically with radiation level. While 18.4% of males from contaminated areas had no sperm that was only the case for 3.0% of males from uncontaminated control areas. Furthermore, there were negative relationships between sperm quality as reflected by reduced sperm velocity and motility, respectively, and radiation.

**Conclusions/Significance:** Our results suggest that radioactive contamination around Chernobyl affects sperm production and quality. We are the first to report an interspecific difference in sperm quality in relation to radioactive contamination.

High frequency of albinism and tumours in free-living birds around Chernobyl

\begin{abstract}
The effects of radioactive contamination on the phenotype of free-living organisms are poorly understood, mainly because of the difficulty of capturing the large numbers of individual specimens that are required to quantify rare events such as albinism and tumour formation. We hypothesized that the frequency of abnormalities like albinism and the frequency of radiation-induced diseases like cancer would increase with the level of background radiation, that the two markers of radiation would be positively correlated, and that the reduction in abundance of animals would be greater in species with a higher frequency of albinism and tumour formation, if these markers reliably reflected poor viability. Here we analyzed the frequency of albinistic feathers and tumours in a sample of 1669 birds captured during 2010–2012 at eight sites around Chernobyl that varied in level of background radiation from 0.02 to more than 200\,\mu\text{Sv/h}. We recorded 111 cases of partial albinism and 25 cases of tumour formation. Nominal logistic models were used to partition the variance into components due to species and background radiation. Radiation was a strong predictor of the two markers in birds, with a small, but significant effect of species for albinism. The slope of the relationship between abundance and radiation in different bird species was significantly inversely correlated with the frequency of albinism and tumours, as was to be expected if a common underlying cause (i.e., radiation) affects both variables. These findings are consistent with the hypothesis that background radiation is a cause of albinism and tumours, that albinism and tumours are biomarkers of radiation exposure, and that high frequencies of albinism and tumours were present despite the low viability of birds with these conditions.

Tumor around eye
Elevated Frequency of Cataracts in Birds from Chernobyl

Timothy Alexander Mousseau¹, Anders Pape Møller²*
¹Department of Biological Sciences, University of South Carolina, Columbia, South Carolina, United States of America, ²Laboratory of Evolution, CNRS UMR 8079, Université Paris-Sud, Orsay, France

Abstract

Background: Radiation cataracts develop as a consequence of the effects of ionizing radiation on the lens of the eye with an opaque lens reducing or eliminating the ability to see. Therefore, we would expect associated with reduced fitness in free-living animals.

Methodology/Principal Findings: We investigated the incidence of lens opacities typical of cataracts in free-living birds in the Chernobyl region in relation to background radiation. The incidence of cataracts of background radiation both in analyses based on a dichotomous score and in analyses of continuous cataracts. The odds ratio per unit change in the regressor was 0.722 (95% CI 0.648, 0.804), which was derived from investigations of radiation cataracts in humans. The relatively small odds ratio may be due to birds with cataracts. We found a stronger negative relationship between bird abundance and background radiation; the frequency of cataracts was higher, but also a direct effect of radiation on abundance, suggesting that effects of radiation on other diseases, food abundance and interactions with other species. The incidence of cataracts with increasing age, suggesting that yearlings and older individuals were more typical of radiation cataract.

Conclusions/Significance: These findings suggest that cataracts are an under-estimated cause of death in birds and, by inference, other vertebrates in areas contaminated with radioactive materials.

Fitness costs of increased cataract frequency and cumulative radiation dose in natural mammalian populations from Chernobyl

Philipp Lehmann1,2, Zbyszek Boratyński3, Tapio Mappes3, Timothy A. Mousseau4 & Anders P. Möller5

A cataract is a clouding of the lens that reduces light transmission to the retina, and it decreases the visual acuity of the bearer. The prevalence of cataracts in natural populations of mammals, and their potential ecological significance, is poorly known. Cataracts have been reported to arise from high levels of oxidative stress and a major cause of oxidative stress is ionizing radiation. We investigated whether elevated frequencies of cataracts are found in eyes of bank voles Myodes glareolus collected from natural populations in areas with varying levels of background radiation in Chernobyl. We found high frequencies of cataracts in voles collected from different areas in Chernobyl. The frequency of cataracts was positively correlated with age, and in females also with the accumulated radiation dose.
Chernobyl Birds Have Smaller Brains

Abstract

**Background:** Animals living in areas contaminated by radioactive material from Chernobyl suffer from increased oxidative stress and low levels of antioxidants. Therefore, normal development of the nervous system is jeopardized as reflected by high frequencies of developmental errors, reduced brain size and impaired cognitive abilities in humans. Alternatively, associations between psychological effects and radiation have been attributed to post-traumatic stress in humans.

**Methodology/Principal Finding:** Here we used an extensive sample of 550 birds belonging to 48 species to test the prediction that even in the absence of post-traumatic stress, there is a negative association between relative brain size and level of background radiation. We found a negative association between brain size as reflected by external head volume and level of background radiation, independent of structural body size and body mass. The observed reduction in brain size in relation to background radiation amounted to 5% across the range of almost a factor 5,000 in radiation level. Species differed significantly in reduction in brain size with increasing background radiation, and brain size was the only morphological character that showed a negative relationship with radiation. Brain size was significantly smaller in yearlings than in older individuals.

**Conclusions/Significance:** Low dose radiation can have significant effects on normal brain development as reflected by brain size and therefore potentially cognitive ability. The fact that brain size was smaller in yearlings than in older individuals implies that there was significant directional selection on brain size with individuals with larger brains experiencing a viability advantage.
Injury to Individuals Causes Population, Community, and Ecosystem Effects
Most of our research includes areas of the highest contamination in addition to control areas. Patchiness of deposition permits disentanglement of radiation, distance from source, and other environmental factors that influence abundance and biodiversity.

Radiological dose reconstruction for birds reconciles outcomes of Fukushima with knowledge of dose-effect relationships

Jacqueline Garnier-Laplace¹, Karine Beaugelin-Seiller¹, Claire Della-Vedova¹, Jean-Michel Métivier¹, Christian Ritz², Timothy A. Mousseau³ & Anders Pape Møller⁴

We reconstructed the radiological dose for birds observed at 300 census sites in the 50-km northwest area affected by the accident at the Fukushima Daiichi nuclear power plant over 2011–2014. Substituting the ambient dose rate measured at the census points (from 0.16 to 31 μGy h⁻¹) with the dose rate reconstructed for adult birds of each species (from 0.3 to 97 μGy h⁻¹), we confirmed that the overall bird abundance at Fukushima decreased with increasing total doses. This relationship was directly consistent with exposure levels found in the literature to induce physiological disturbances in birds. Among the 57 species constituting the observed bird community, we found that 90% were likely chronically exposed at a dose rate that could potentially affect their reproductive success. We quantified a loss of 22.6% of the total number of individuals per increment of one unit log₁₀-transformed total dose (in Gy), over the four-year post-accident period in the explored area. We estimated that a total dose of 0.55 Gy reduced by 50% the total number of birds in the study area over 2011–2014. The data also suggest a significant positive relationship between total dose and species diversity.

**Abstract** Tree growth has been hypothesized to provide a reliable indicator of the state of the external environment. Elevated levels of background ionizing radiation may impair growth trajectories of trees by reducing the annual drought or their interactions with background radiation. Elevated temperatures suppressed individual growth rates in particular years. Finally, the negative effects of radioactive contaminants were particularly pronounced in

Highly reduced mass loss rates and increased litter layer in radioactively contaminated areas

Timothy A. Mousseau · Gennadi Milinevsky · Jane Kenney-Hunt · Anders Pape Møller

Abstract The effects of radioactive contamination from Chernobyl on decomposition of plant material still remain unknown. We predicted that decomposition rate would be reduced in the most contaminated sites due to an absence or reduced densities of soil invertebrates. If microorganisms were the main agents responsible for decomposition, exclusion of large soil invertebrates should not affect decomposition. In September 2007 we deposited 572 bags loss was 40 % lower in the most contaminated sites relative to sites with a normal background radiation level for Ukraine. Similar reductions in litter mass loss were estimated for individual litter bags, litter bags at different sites, and differences between litter bags at pairs of neighboring sites differing in level of radioactive contamination. Litter mass loss was slightly greater in the presence of large soil invertebrates than in their absence. The thickness of the for-
Review

Are Organisms Adapting to Ionizing Radiation at Chernobyl?

Anders Pape Møller¹,²,* and Timothy Alexander Mousseau³

Numerous organisms have shown an ability to survive and reproduce under low-dose ionizing radiation arising from natural background radiation or from nuclear accidents. In a literature review, we found a total of 17 supposed cases of adaptation, mostly based on common garden experiments with organisms only deriving from typically two or three sampling locations. We only found one experimental study showing evidence of improved resistance to radiation. Finally, we examined studies for the presence of hormesis (i.e., superior fitness at low levels of radiation compared with controls and high levels of radiation), but found no evidence to support its existence. We conclude that rigorous experiments based on extensive sampling from multiple sites are required.
What does this all mean?

• Contrary to governmental and media reports, there is now an abundance of information demonstrating consequences (i.e. injury) to individuals, populations, species, and ecosystem function stemming from the low dose radiation due to the Chornobyl and Fukushima disasters.

• Effects appear to be proportional to dose.

• There is no evidence for any kind of threshold below which effects are not seen.
