Quality Programming Begets Software Quality

Joe Jarzombek, Director for Software Assurance in the National Cyber Security Division (NCSD) of the Department of Homeland Security (DHS, CROSSTalk’s co-sponsor), has given many keynote presentations at conferences in which he advocates the need for security-enhanced processes and practices. His message at the Software Engineering Process Group Conference in March was a snapshot of the session he facilitated on February 8, 2008, on “Security-Enhanced Quality Assurance and Project Management: Mitigating Risks to the Enterprise” at the Defense Acquisition University’s (DAU) Advanced Software Acquisition Management course. His opening message set the theme for his DAU presentation and this issue of CROSSTalk. Jarzombek said, “With today’s global supply chain for information technology and software, the processes associated with software engineering, quality assurance (QA), and project management must explicitly address security risks posed by exploitable software. However, traditional processes do not explicitly address software security risks that can be passed from projects to using organizations.

“Mitigating supply chain risks requires an understanding and management of suppliers’ process capabilities, products and services. Enterprise risks stemming from the supply chain are influenced by suppliers and acquisition projects (including procurement, QA, and testing). Software assurance processes and practices span development and acquisition.

“Derived (non-explicit) security requirements should be elicited and considered. QA and testing can integrate security considerations in their practices to enhance value in mitigating risks to the enterprise.”

He then asked the audience, “What legacy do you intend to leave from the programs in which you have project responsibilities? Is it one that contributes to a more resilient system and enterprise or one that was simply good enough to get the customer to accept without an understanding of the residual risk passed to the end user?”

Along those lines, this month’s issue of CROSSTalk deals with software quality. In his article The Software Quality Challenge, Watts S. Humphrey discusses how today’s more complex software offers greater challenges in the areas of safety, security and reliability. Capers Jones talks about two measures that have a strong influence on the outcomes of software projects in Measuring Defect Potentials and Defect Removal Efficiency. Asking the tantalizing question, “Would your company like to save $100,000 per day?” Thomas D. Neff offers insights into how that is possible in Quality Processes Yield Quality Products; while Dr. Paul Anderson discusses the advantages and limitations of using static-analysis tools in The Use and Limitations of Static-Analysis Tools to Improve Software Quality. Next, D. Richard Kuhn, Dr. Yu Lei, and Dr. Raghu Kacker offer new tools for automating the production of complete test cases covering up to 6-way combinations in Automated Combinatorial Test Methods – Beyond Pairwise Testing, and Dr. Jeffrey Voas gives us a look at the misunderstood term software quality in Software Quality Unpeeled.

For additional information, I want to remind everybody that DHS’ NCSD offers free resources related to security-enhanced quality assurance, project management, and software engineering via their software assurance and BuildSecurityIn Web sites at: <www.us-cert.gov/swa> and <https://buildsecurityin.us-cert.gov>. More can also be learned at the World Congress for Software Quality, a major international gathering of software quality professionals that will take place September 15-18, 2008 in Bethesda, Maryland. For more information on the conference, visit <www.asq.org/conferences/wcsq>.

Finally, I would like to thank Beth Starrett for the exemplary work she has done over the past eight years as publisher of CROSSTalk. During her tenure at the helm the publication has thrived, and has broadened both its scope and depth in the field of defense software engineering. With her departure, we welcome Kasey Thompson as our new publisher. Kasey has long been associated with CROSSTalk, and we look forward to a new era of cutting-edge articles, innovative features, and ever-evolving quality information on the subjects that you, our readers, demand.

Managing Director
The Software Quality Challenge

Watts S. Humphrey
The Software Engineering Institute

Many aspects of our lives are governed by large, complex systems with increasingly complex software, and the safety, security, and reliability of these systems has become a major concern. As the software in today's systems grows larger, it has more defects, and these defects adversely affect the safety, security, and reliability of the systems. This article explains why the common test-and-fix software quality strategy is no longer adequate, and characterizes the properties of the quality strategy we must pursue to solve the software quality problem in the future.

Today, many of the systems on which our lives and livelihoods depend are run by software. Whether we fly in airplanes, file taxes, or wear pacemakers, our safety and well being depend on software. With each system enhancement, the size and complexity of these systems increase, as does the likelihood of serious problems. Defects in video games, reservations systems, or accounting programs may be inconvenient, but software defects in aircraft, automobiles, air traffic control systems, nuclear power plants, and weapons systems can be dangerous.

Everyone depends on transportation networks, hospitals, medical devices, public utilities, and the international financial infrastructure. These systems are all run by increasingly complex and potentially defective software systems. Regardless of whether these large life-critical systems are newly developed or composed from modified legacy systems, to be safe or secure, they must have quality levels of very few defects per million parts.

Modern, large-scale systems typically have enormous requirements documents, large and complex designs, and millions of lines of software code. Uncorrected errors in any aspect of the design and development process generally result in defects in the operational systems. The defect levels of such operational systems are typically measured in defects per thousand lines of code. A one million line-of-code system with the typical quality level of one defect per 1,000 lines would have 1,000 undiscovered defects, while any reasonably safe system of this scale must have only a very few defects, certainly less than 10.

The Need for Quality Software

Before condemning programmers for doing sloppy work, it is appropriate to consider the quality levels of other types of printed media. A quick scan of most books, magazines, and newspapers will reveal at least one and generally more defects per page while even poor-quality software has much less than one defect per listing page. This means that the quality level of even poor-quality software is higher than that obtained for other kinds of human written text. Programming is an exacting business, and these professionals are doing extraordinarily high quality work. The only problem is that based on historical trends, future systems will be much larger and more complex than today, meaning that just to maintain today's defect levels, we must do much higher quality work in the future.

To appreciate the challenge of achieving 10 or fewer defects per million lines of code, consider what the source listing for such a program would look like. The listing for a 1,000-line program would fill 40 text pages; a million-line program would take 40,000 pages. Clearly, finding all but 10 defects in 40,000 pages of material is humanly impossible. However, we now have complex life-critical systems of this scale and will have much larger ones in the relatively near future. So we must do something, but what? That is the question addressed in this article.

Why Defective Systems Work

To understand the software quality problem, the first question we must answer is If today's software is so defective, why aren't there more software quality disasters? The answer is that software is an amazing technology. Once you test it and fix all of the problems found, that software will always work under the conditions for which it was tested. It will not wear out, rust, rot, or get tired. The reason there are not more software disasters is that testers have been able to exercise these systems in just about all of the ways they are typically used. So, to solve the software quality problem, all we must do is keep testing these systems in all of the ways they will be used. So what is the problem?

The problem is complexity. The more complex these systems become, the more different ways they can be used, and the more ways users can use them, the harder it is to test all of these conditions in advance. This was the logic behind the beta-testing strategy started at IBM with the OS/360 system more than 40 years ago. Early copies of the new system releases were sent to a small number of trusted users and IBM then fixed the problems they found before releasing the public version. This strategy was so successful that it has become widely used by almost all vendors of commercial software.

Unfortunately, however, the beta-testing strategy is not suitable for life-critical systems. The V-22 Osprey helicopter, for example, uses a tilting wing and rotor system in order to fly like an airplane and land like a helicopter. In one test flight, the hydraulic system failed just as the pilot was tilting the wing to land. While the aircraft had a built-in back-up system to handle such failures, the aircraft had not been tested under those precise conditions, and the defect in the back-up system's software had not been found. The defect caused the V-22 to become unstable and crash, killing all aboard.

The problem is that as systems become more complex, the number of possible ways to use these systems grows exponentially. The testing problem is further complicated by the fact that the way such systems are configured and the environments in which they are used also affect the way the software is executed. Table 1 lists some of the variations that must be considered in testing complex systems. An examination of the number of possibilities for even relatively simple systems shows why it is impractical to test all possibilities for any complex system. So why is complex software so defective?

Some Facts

Software is and must remain a human-produced product. While tools and techniques have been devised to automate the production of code once the requirements
and design are known, the requirements and design must be produced by people. Further, as systems become increasingly complex, their requirements and design grow increasingly complex. This complexity then leads to errors, and these errors result in defects in the requirements, design, and the operational code itself. Thus, even if the code could be automatically generated from the defective requirements and design, that code would reflect these requirements and design defects and, thus, still be defective. 

When people design things, they make mistakes. The larger and more complex their designs, the more mistakes they are likely to make. From course data on thousands of experienced engineers learning the Personal Software Process (PSP®), it has been found that developers typically inject about 100 defects into every 1,000 lines of the code they write [1]. The distribution for the total defects injected by 810 experienced developers at the beginning of PSP training is shown by the total bars in Figure 1. While there is considerable variation and some engineers do higher-quality work, just about everybody injects defects.

Developers use various kinds of tools to generate program code from their designs, and they typically find and fix about half of their defects during this process. This means that about 50 defects per 1,000 lines of code remain at the start of initial testing. Again, the distribution of the defects found in initial testing is also shown by the test bars in Figure 1.

Developers generally test their programs until they run without obvious failures. Then they submit these programs to systems integration and testing where they are combined with other similar programs into larger and larger sub-systems and systems for progressively larger-scale testing. The defect content of programs entering systems testing typically ranges between 10 and 20 defects per 1,000 lines.

The most disquieting fact is that testing can only find a fraction of the defects in a program. That is, the more defects a program contains at test entry, the more it is likely to have at test completion. The reason for this is the point previously made about extensive testing. Clearly, if defects are randomly sprinkled throughout a large and complex software system, some of them will be in the most rarely used parts of the system and others will be in those parts that are only exercised under failure conditions. Unfortunately, these rarely used parts are the ones most likely to be exercised when such systems are subjected to the stresses of high transaction volume, accidents, failures, or military combat.

**The Defect Removal Problem**

A defect is an incorrect or faulty construction in a product. For software, defects generally result from mistakes that the designers or developers make as they produce their products. Examples are oversights, misunderstandings, and typos. Furthermore, since defects result from mistakes, they are not logical. As a consequence, there is no logical or deductive process that could possibly find all of the defects in a system. They could be anywhere, and the only way to find all of the defects with testing is to exhaustively test every path, function, or system condition.

This leads to the next question which concerns the testing objective: “Must we find all of the defects, or couldn’t we just find and fix those few that would be dangerous?” Obviously, we only need to fix the defects that would cause trouble, but there is no way to determine which defects these are without examining all of the defects. For example, a complex design defect that produced a confusing operator message could pose no danger while a trivial typographical mistake that changed a number to a yes could be very dangerous. Since there is no way to tell in advance which defects would be damaging, we must try to find them all. Then, after finding them, we must fix at least all of the ones that would be damaging.

**The Testing Problem**

Since defects could be anywhere in a large software system, the only way testing could find them all would be to completely test every segment of code in the entire program. To understand this issue, consider the program structure in Figure 2. This code fragment has one branch instruction at point B; three segments: A to B, B to C, and B to D; and two possible paths or routes through the fragment: A-B-C and A-B-D. So, for a program fragment like this, there could be defects on any of the code segments as well as in the branch instruction itself.

For a large program, the numbers of possible paths or routes through a program can vary by program type, but pro...
Software Quality

grams generally have about one branch instruction for every 10 or so lines of code. This means that a million-line program would typically have about 100,000 branch instructions. To determine the magnitude of the testing problem for such a system, we must determine the number of test paths through a network of 100,000 switches. Here, from Figure 3, we can calculate that, for a simple network of 16 switches, there are 70 possible paths from A to B. As shown in Table 2, the number of possible paths through larger networks grows rapidly with 100 switches having 184,756 possible paths and 400 switches having 1.38E+11 possible paths. Clearly, the number of possible paths through a system with 100,000 switches could, for practical purposes, be considered infinite. Furthermore, even if comprehensive path testing were possible, more than path testing would be required to uncover the defects that involved timing, synchronization, or unusual operational conditions.

Conclusions on Testing

At this point, several conclusions can be drawn. First, today’s large-scale systems typically have many defects. Second, these defects generally do not cause problems as long as the systems are used in ways that have been tested. Third, because of the growing complexity of modern systems, it is impossible to test all of the ways in which such systems could be used. Fourth, when systems are stressed in unusual ways, their software is most likely to encounter undiscovered defects. Fifth, under these stressful conditions, these systems are least likely to operate correctly or reliably.

Therefore, with the current commonly used test-based software quality strategy, large-scale life-critical systems will be least reliable in emergencies – and that is when reliability is most important.

Successful Quality Strategies

Organizations have reached quality levels of a few defects per million parts, but these have been with manufacturing and not design or development processes. In the manufacturing context, the repetitive work is performed by machines, and the quality challenge is to consistently and properly follow all of the following steps:

- Establish quality policies, goals, and plans.
- Properly set up the machines.
- Keep the machines supplied with high-quality parts and materials.
- Maintain the entire process under continuous statistical control.
- Evaluate the machine outputs.
- Properly handle all deviations and problems.
- Suitably package, distribute, or otherwise handle the machine outputs.
- Consistently strive to improve all aspects of the production and evaluation processes.

While these eight steps suggest some approaches to consider for software development, they are not directly applicable for human-intensive work such as design and development. However, by considering an analogous approach with people instead of machines, we begin to see how to proceed.

The Eight Elements of Software Quality Management

The eight steps required to consistently produce quality software are based on the five basic principles of software quality shown in the Software Quality Principles sidebar. With these principles in mind, we can now define the eight steps required for an effective software quality initiative.

1. Establish quality policies, goals, and plans.
2. Properly train, coach, and support the developers and their teams.
3. Establish and maintain a requirements quality-management process.
4. Establish and maintain statistical control of the software engineering process.
5. Review, inspect, and evaluate all product artifacts.
6. Evaluate all defects for correction and
Software Quality Principles*

1. Properly managed quality programs reduce total program cost, increase business value and quality of delivered products, and shorten development times.
   1.1. If cost or development times increase, the quality program is not being properly implemented.
   1.2. The size of a product, including periodic reevaluation of size as changes occur, must be estimated and tracked.
   1.3. Schedules, budgets, and quality commitments must be mutually consistent and based on sound historical data and estimating methods.
   1.4. The development approach must be consistent with the rate of change in requirements.

2. To get quality work, the customer must demand it.
   2.1. Attributes that define quality for a software product must be stated in measurable terms and formally agreed to between developers and customers as part of the contract. Any instance of deviation from a specified attribute is a defect.
   2.2. The contract shall specify the agreed upon quality level, stated in terms of the acceptable quantity or ratio of deviations (defects) in the delivered product.

3. The developers must feel personally responsible for the quality of the products they produce.
   3.1. The development teams must plan their own work and negotiate their commitments with management and the customer.
   3.2. Software managers must provide appropriate training for developers.
   3.3. A developer is anyone who produces a part of the product, be it a designer, documentation, coder, or systems designer.

4. For the proper management of software development projects, the development teams themselves must plan, measure, and control the work.
   4.1. Project teams must have knowledge and experience in the relevant technologies and applications domains commensurate with project size and other risk factors.
   4.2. Removal yield at each step and in total pre-delivery must be measured.
   4.3. Effort associated with each activity must be recorded.
   4.4. Defects discovered by each appraisal method must be recorded.
   4.5. Measurements must be recorded by those performing the activity and be analyzed by both developers and managers.

5. Software management must recognize and reward quality work.
   5.1. Projects must utilize a combination of appraisal methods sufficient to verify the agreed defect levels.
   5.2. Managers must use measures to ensure high quality and improve processes.
   5.3. Managers must use measurements with due respect for individuals.

* These principles were defined by a group of 13 software quality experts convened by Taz Daughtrey. The experts are: Carol Dekkers, Gary Gack, Tom Gilb, Watts Humphrey, Joe Jazwinski, Capers Jones, Stephen Kan, Herb Krasner, Gary McGraw, Patricia McQuaid, Mark Pauk, Colin Tully, and Jerry Weinberg.

---

July 2008
mount. However, the requirements quality problem is complicated by two facts.

First, the quality measures must not be abstract characteristics of a requirements document; they should be precise and measurable items such as defect counts from requirements inspections or counts of requirements defects found in system test or customer use. However, to be most helpful, these quality measures must also address the precise understanding the developers themselves have of the requirements regardless of what the requirements originators believe or how good a requirements document has been produced. The developers will build what they believe the requirements say and not what the requirements developers intended to say. This means that the quality-management problem the requirements process must address is the transfer of understanding from the requirements experts to the software developers.

The second key requirements fact is that the requirements are dynamic. As people learn more about what the users need and what the developers can build, their views of what is needed will change. This fact enormously complicates the requirements-management problem. The reason is that people's understanding of their needs evolves gradually and often without any conscious appreciation of how much their views have changed. There is also a time lag: Even when the users know that their needs have changed, it takes time for them to truly understand their new ideas and to communicate them to the developers. Even after the developers understand the changes, they cannot just drop everything and switch to the new version.

To implement a change, the design and implementation implications of every requirements change must be appraised; plans, costs, and commitments adjusted; and agreement reached on how to incorporate this new understanding into the development work. This means that the requirements must be recognized as evolving through a sequence of versions while the development estimates, plans, and commitments are progressing through a similar but delayed sequence of versions. And finally, the product itself will ultimately be produced in a further delayed sequence of versions. The quality management problem concerns managing the quality and maintaining the synchronization of this sequence of parallel requirements, plan, design, and product versions.

**Step 4: Statistical Process Control**

While statistical process control is a large subject, we need only discuss two aspects: process management and continuous process improvement. The first aspect, process management, is discussed here, and process improvement is addressed in Step 8.

The first step in statistical process management is to redefine the quality management strategy. To achieve high levels of software quality, it is necessary to switch from looking for defects to managing the process. As noted earlier, to achieve a quality level of 10 defects per million lines with current software quality management methods, the developers would have to find and fix all but 10 of the 10,000 to 20,000 defects in a program with a 40,000 page listing. Unless someone devises a magic machine that could flawlessly identify every software defect, it would be clearly impossible to improve human search and analysis skills to this degree. Therefore, achieving these quality levels through better testing, reviews, or inspections is not feasible.

A more practical strategy is to measure and manage the quality of the process used to produce the program's parts. If, for example, we could devise a process that would consistently produce 1,000-line modules that each had less than a one percent chance of having a single defect, a system of 1,000 of these modules would likely have less than 10 defects per million lines. One obvious problem with this strategy concerns our ability to devise and properly use such a process.

There has been considerable progress in producing and using such a process. This is accomplished by measuring each developer's process and producing a Process Quality Index (PQI). The TSP quality profile, which forms the basis for the PQI measure, is shown in Figure 5 [6]. Then, the developers and their teams use standard statistical process management techniques to manage the quality of all dimensions of the development work [7]. Data on early TSP teams show that by following this practice, quality is substantially improved [8].

**Step 5: Quality Evaluation**

Quality evaluation has two elements: evaluating the quality of the process used to produce each product element, and evaluating the quality of the products produced by that process. The reason to measure and evaluate process quality, of course, is to guide the process-improvement activities discussed in Step 8. The Capability Maturity Model® Integration (CMMI®) model and appraisal methods were developed to guide process-quality assessments, and the TSP process was developed to guide organizations in defining, using, and improving high-quality processes as well as in measuring, managing, and evaluating product quality.

To evaluate process quality, the developers and their teams must gather data on their work, and then evaluate these data against the goals they established in their quality plan. If any process or process step falls below the team-defined quality threshold, the resulting products must be evaluated for repair, redevelopment, or replacement, and the process must be brought into conformance. These actions must be taken for every process step and especially before releasing any products from development into testing. In product evaluation, the system integration and testing activities are also measured and evaluated to determine if the final product has reached a suitable quality level or if some remedial action is required.

---

*Capability Maturity Model and CMMI are registered in the U.S. Patent and Trademark Office by Carnegie Mellon University.*
Step 6: Defect Analysis

Regardless of the quality management methods used (i.e., International Organization for Standardization, correctness-by-construction, or AS9100) continuous improvement strategies such as those defined by CMMI and TSP should be applied to the improvement process itself. This means that the process quality measures, the evaluation methods, and the decision thresholds must also be considered as important aspects of continuous process improvement. Furthermore, since every developer, team, project, and organization is different, it means that this continuous improvement process must involve every person on every development team and on every project in the organization.

Conclusion

While we face a major challenge in improving software quality, we also have substantial and growing quality needs. It should now be clear to just about everyone in the software business that the current test-based quality strategy has reached a dead end. Software development groups have struggled for years to get quality improvements of 10 to 20 percent by trying different testing strategies and methods, with little to no improvement, and by working harder.

The quality improvements required are vast, and such improvements cannot be achieved by merely bulling ahead with the test-based methods of the past. While the methods described in this article have not yet been fully proven for software, we now have a growing body of evidence that they will work – at least better than what we have been doing. What is more, this quality strategy uses the kinds of data-based methods that can guide long-term continuous improvement. In addition to improving quality, this strategy has also been shown to save time and money.

Finally, and most importantly, software quality is an issue that should concern everyone. Poor quality software now costs each of us time and money. In the immediate future, it is also likely to threaten our lives and livelihoods. Every one of us, whether a developer, a manager, or a user, must insist on quality work; it is the only way we will get the kind of software we all need.

Acknowledgements

My thanks to Bob Cannon, David Carrington, Tim Chick, Taz Daughtrey, Harry Levinson, Julia Mullaney, Bill Nichols, Bill Peterson, Alan Willett, and Carol Woody for reviewing this article and offering their helpful suggestions. I also much appreciate the constructive suggestions of the CROSSTalk editorial board.

2009 Systems and Software Technology Conference<br>Salt Lake City, UT<br><www.sstc-online.org>  

**Coming Events**: Please submit coming events that are of interest to our readers at least 90 days before registration. E-mail announcements to: nicole.kentta@hill.af.mil.

## Web Sites

### Software Quality Profile
www.sei.cmu.edu/publications/articles/quality-profile/index.html  
This article proposes innovative solutions to today's emerging software quality issues.

### Society for Software Quality
www.ssq.org  
The Society for Software Quality (SSQ) is a membership organization for those interested in promoting quality as a universal goal for software. The SSQ promotes increased knowledge and interest in the technology associated with the development and maintenance of quality software.

### Better Software Magazine
www.stpmag.com  
*Better Software* is the magazine for software professionals who care about quality. Each issue addresses relevant, timely information to help with building better software. *Better Software* delivers in-depth articles on testing, tools, defect tracking, metrics, and management, and is the only commercial magazine exclusively dedicated to software professionals.

### Software Test and Performance Magazine
www.stpmag.com  
*Software Test & Performance* is written for software and application development managers, project managers, team leaders, and test and quality assurance managers. Articles in the magazine provide useful information to help those in the field understand trends and emerging technologies, come to grip with new and timeless challenges, adopt new best practices concepts, and ultimately make better decisions to improve software quality.

### Handbook of Software Quality Assurance
The software industry has witnessed a dramatic rise in the impact and effectiveness of software quality assurance. From its infancy when a handful of software pioneers explored the first applications of quality assurance to the development of software, software quality assurance has become integrated into all phases of software development. This handbook capitalizes on the talents and skills of the experts who deal with the implementation of software quality assurance on a daily basis.
Measuring Defect Potentials and Defect Removal Efficiency®

Capers Jones
Software Productivity Research, LLC

There are two measures that have a strong influence on the outcomes of software projects: 1) defect potentials and 2) defect removal efficiency. The term defect potentials refers to the total quantity of bugs or defects that will be found in five software artifacts: requirements, design, code, documents, and bad fixes, or secondary defects. The term defect removal efficiency refers to the percentage of total defects found and removed before software applications are delivered to customers. As of 2007, the average for defect potentials in the United States was about five defects per function point. The average for defect removal efficiency in the United States was only about 85 percent. The average for delivered defects was about 0.75 defects per function point.

The phrase defect removal efficiency refers to the percentage of the defect potentials that will be removed before the software application is delivered to its users or customers. As of 2007, the average for defect removal efficiency in the U.S. was about 85 percent.

If the average defect potential is five bugs – or defects – per function point and removal efficiency is 85 percent, then the total number of delivered defects will be about 0.75 per function point. However, some forms of defects are harder to find and remove than others. For example, requirements defects and bad fixes are much more difficult to find and eliminate than coding defects.

At a more granular level, the defect removal efficiency against each of the five defect categories is approximate in Table 2.

Note that the defects discussed in this section include all severity levels, ranging from severity 1: show stoppers, down to severity 4: cosmetic errors. Obviously, it is important to measure defect severity levels as well as recording numbers of defects.2

There are large ranges in terms of both defect potentials and defect removal efficiency levels. The best in class organizations have defect potentials that are below 2.50 defects per function point coupled with defect removal efficiencies that top 95 percent across the board.

Defect removal efficiency levels peak at about 99.5 percent. In examining data from about 13,000 software projects over a period of 40 years, only two projects had zero defect reports in the first year after release.

This is not to say that achieving a defect removal efficiency level of 100 percent is impossible, but it is certainly very rare.

Organizations with defect potentials higher than seven per function point coupled with defect removal efficiency levels of 75 percent or less can be viewed as exhibiting professional malpractice. In other words, their defect prevention and defect removal methods are below acceptable levels for professional software organizations.

Most forms of testing average only about 30 to 35 percent in defect removal efficiency levels and seldom top 50 percent. Formal design and code inspections, on the other hand, often top 85 percent in defect removal efficiency and average about 65 percent.

As can be seen from the short discussions here, measuring defect potentials and defect removal efficiency provide the most effective known ways of evaluating various aspects of software quality control. In general, improving software quality requires two important kinds of process improvement: 1) defect prevention and 2) defect removal.

The phrase defect prevention refers to
technologies and methodologies that can lower defect potentials or reduce the numbers of bugs that must be eliminated. Examples of defect prevention methods include joint application design, structured design, and also participation in formal inspections.

The phrase defect removal refers to methods that can either raise the efficiency levels of specific forms of testing or raise the overall cumulative removal efficiency by adding additional kinds of review or test activity. Of course, both approaches are possible at the same time.

In order to achieve a cumulative defect removal efficiency of 95 percent, it is necessary to use approximately the following sequence of at least eight defect removal activities:

- Design inspections.
- Code inspections.
- Unit tests.
- New function tests.
- Regression tests.
- Performance tests.
- System tests.
- External beta tests.

To go above 95 percent, additional removal stages are needed. For example, requirements inspections, test case inspections, and specialized forms of testing, such as human factors testing, add to defect removal efficiency levels.

Since each testing stage will only be about 30 percent efficient, it is not feasible to achieve a defect removal efficiency level of 95 percent by means of testing alone. Formal inspections will not only remove most of the defects before testing begins, it also raises the efficiency level of each test stage. Inspections benefit testing because design inspections provide a more complete and accurate set of specifications from which to construct test cases.

From an economic standpoint, combining formal inspections and formal testing will be cheaper than testing by itself. Inspections and testing in concert will also yield shorter development schedules than testing alone. This is because when testing starts after inspections, almost 85 percent of the defects will already be gone. Therefore, testing schedules will be shortened by more than 45 percent.

When IBM applied formal inspections to a large database project, delivered defects were reduced by more than 50 percent from previous releases, and the overall schedule was shortened by about 15 percent. Testing itself was reduced from two shifts over a 60-day period to one shift over a 40-day period. More importantly, customer satisfaction improved to good from prior releases where customer satisfaction previously had been very poor.

**Measurement of Defect Potentials and Defect Removal Efficiency**

Measuring defect potentials and defect removal efficiency levels are among the easiest forms of software measurement, and are also the most important. To measure defect potentials it is necessary to keep accurate records of all defects found during the development cycle, which is something that should be done as a matter of course. The only difficulty is that private forms of defect removal such as unit testing will need to be done on a volunteer basis.

Measuring the numbers of defects found during reviews, inspections, and testing is also straightforward. To complete the calculations for defect removal efficiency, customer-reported defect reports submitted during a fixed time period are compared against the internal defects found by the development team. The normal time period for calculating defect removal efficiency is 90 days after release.

As an example, if the development and testing teams found 900 defects before release, and customers reported 100 defects in the first three months of usage, it is apparent that the defect removal efficiency would be 90 percent.

Unfortunately, although measurements of defect potentials and defect removal efficiency levels should be carried out by 100 percent of software organizations, the frequency of these measurements circa 2008 is only about five percent of U.S. companies. In fact, more than half of U.S. companies do not have any useful quality metrics at all. More than 80 percent of U.S. companies, including the great majority of commercial software vendors, have only marginal quality control and are much lower than the optimal 95 percent defect removal efficiency level. This fact is one of the reasons why so many software projects fail completely or experience massive cost and schedule overruns. Usually failing projects seem to be ahead of schedule until testing starts, at which point huge volumes of unanticipated defects stop progress almost completely.

As it happens, projects that average about 95 percent in cumulative defect removal efficiency tend to be optimal in several respects. They have the shortest development schedules, the lowest development costs, the highest levels of customer satisfaction, and the highest levels of team morale. This is why measures of defect potentials and defect removal efficiency levels are important to the industry as a whole; these measures have the greatest impact on software performance of any known metrics.

Additionally, as an organization progresses from the U.S. average of 85 percent in defect removal efficiency up to 95 percent, the saved money and shortened development schedules result because most schedule delays and cost overruns are due to excessive defect volumes during testing. However, to climb above 95 percent defect removal efficiency up to 99 percent does require additional costs. It will be necessary to perform 100 percent inspections of every deliverable, and testing will require about 20 percent more test cases than normal.

It is an interesting sociological observation that measurements tend to change human behavior. Therefore, it is important to select measurements that will cause behavioral changes in positive and beneficial directions. Measuring defect potentials and defect removal efficiency levels have been noted to make very beneficial improvements in software development practices.

When these measures were introduced into large corporations such as IBM and ITT, in less than four years the volumes of delivered defects had declined by more than 50 percent, maintenance costs were reduced by more than 40 percent, and development schedules were shortened by more than 15 percent. There are no other measurements that can yield such positive benefits in such a short time span. Both customer satisfaction and employee morale improved, too, as a direct result of the reduction in defect potentials and the increase in defect removal efficiency levels.

**Reference**

**Notes**

1. The averages for defect potentials are derived from studies of about 600 companies and 13,000 projects. Non-disclosure agreements prevent the identification of most companies. However some companies such as IBM and ITT have provided data on defect potentials and removal efficiency levels.

2. The normal period for measuring defect removal efficiency starts with requirements inspections and ends 90 days after delivery of the software to its users or customers. Of course, there
are still latent defects in the software that will not be found in 90 days, but having a 90-day interval provides a standard benchmark for defect removal efficiency. It might be thought that extending the period from 90 days to six months or 12 months would provide more accurate results; however, updates and new releases usually come out after 90 days, so these would dilute the original defect counts. Latent defects found after the 90-day period can exist for years, but on average about 50 percent of residual latent defects are found each year. The results vary with number of users of the applications. The more users, the faster residual latent defects are discovered.

3. Formal design and code inspections are the most effective defect removal activity in the history of software, and are also very good in terms of defect prevention. Once participants in inspections observe various kinds of defects in the materials being inspected, they tend to avoid those defects in their own work. All software projects larger than 1,000 function points should use formal design and code inspections.

CALL FOR ARTICLES

If your experience or research has produced information that could be useful to others, CROSSTalk can get the word out. We are specifically looking for articles on software-related topics to supplement upcoming theme issues. Below is the submittal schedule for three areas of emphasis we are looking for:

Data and Data Management  
December 2008  
Submission Deadline: July 18, 2008

Engineering for Production  
January 2009  
Submission Deadline: August 15, 2008

Software Measurement  
February 2009  
Submission Deadline: September 12, 2008

Please follow the Author Guidelines for CROSSTalk, available on the Internet at <www.stsc.hill.af.mil/crosstalk>. We accept article submissions on software-related topics at any time, along with Letters to the Editor and BACKTalk. We also provide a link to each monthly theme, giving greater detail on the types of articles we’re looking for at <www.stsc.hill.af.mil/crosstalk/theme.html>.
If your company developed software that ran tools capable of propelling big objects long distances, measured accuracy in miles, and increased its accuracy to inches, you might save your customer millions of dollars. This actually happened [1]. If your company refined its software development processes so that your unit testing department found zero errors in a three-year period, you might eliminate unit testing and move those testers into other types of testing, saving many dollars with every release. This also happened [2]. If your customer asked you to speed up your next software delivery by 50 percent and guarantee no flaws in the delivered product, could you do it without incurring any extra costs or sacrificing other projects? One company did [3].

You may figure those goals are impossible for your organization to achieve or you do not have enough money to make it happen. If so, you are wrong. Right now open a Web browser, type <www.sei.cmu.edu>, and hit enter. If your organization does software development, search for Capability Maturity Model Integration for Development (CMMI-DEV). If you are an acquisition organization, search for CMMI-Acquisition (ACQ). All organizations should check out People Capability Maturity Model (PCM).

These models are all instantiations of Total Quality Management (TQM), the method that turned low-quality Japanese trinkets into high-quality automobiles, electronics, cameras, and many other products [4]. Because these models are different views of the same paradigm, you can also use them in other areas. One company used a predecessor of the CMMI-DEV and achieved the model’s highest level of process maturity in software development. That company’s hardware people realized the software folks really had their act together. They got jealous and sought the software secret. When they were shown the CMM, they said, “We could use that if we just change a few of the terms. Instead of talking about managing software requirements, we would manage hardware requirements.” Before long, that entire group was achieving record low manufacturing defects, record high profits, record high customer and employee satisfaction, record low employee turnover, and many more positive effects [3].

If the rewards from doing this are so great, why do so few companies achieve CMMI Level 5 – the highest level of process maturity? I contend it is because they do not execute their continuous process improvement (CPI) effort properly. There are many ways to do it right, but even more ways to do it wrong. If you would like to help ensure success in your CPI effort, read this article and get started. Before long you could very well be producing (or acquiring) software of exceptional quality, precisely meeting customer requirements, and incurring minimal maintenance costs.

Based on 15 years of CPI experience, here are some items you might consider when starting or reinvigorating your CPI effort. While they are no guarantee that you will reach the CMMI pinnacle, they can help you avoid pitfalls that snap many such efforts. (Throughout this list, we and our refer to the Nuclear Weapons Effects Division Process Improvement Team [PIT]):

- Do not try to inspects in quality. All too often, people believe they can have ad-hoc development processes, then use an inspection process at the end and effectively remove all defects, yielding a quality product. It just will not happen. My experience shows that only a small portion of defects are actually removed if the attempt is only at the end. Inspections in every phase of the process are good, just do not wait to the end. Inspect on a daily basis to approach zero. Large expense, little return – not a good business decision.
- Do not look for a quick fix. I have learned to fear when a senior manager goes to a conference where process improvement is discussed. Inevitably they return with the latest fad and want to implement it by week’s end. It takes between two and three years to get CPI institutionalized. Your processes did not get screwed up overnight; they will not get fixed overnight, either.
- Hold people accountable. This is the biggest key to any CPI effort. If you create a meager CPI plan complete with a feedback loop for improvements, then hold people accountable to following it – you will make great progress in relatively little time. I have experienced both sides of this and can vouch that not holding them accountable will guarantee failure, and always holding them accountable is more likely to guarantee success. However, you cannot hold them accountable for six months and then give up because it is not working. Refer to the second point above.
- Do not aim for a certain level of improvement. Never state, “We want to achieve CMMI Level 3 by ___ date.” What matters are the qualities exhibited, not the score obtained. Your primary emphasis must be to institutionalize CPI. Once that is accomplished, the rest will fall into place. If your aim is Level 3, once you reach it, you will not have any objective left and you will begin backsliding. However, if you emphasize CPI, once you reach Level 5, you will be thinking about what Level 6 (if there was one) would look like or you will seek other company areas that could benefit from your CPI attitude. Levels are just indicators of your progress.
- Do not follow the CMMIs in the order they are written. They are written so that one size fits all. As you and I know, even though one size fits all, it rarely looks good. You are much better off finding those areas of the CMMI currently giving you the most headaches and work on those first. If that does not work for you or you have many headaches, take a new project.

Would your company like to save $100,000 per day? Would you like to surge an urgent project’s delivery time by 50 percent and deliver zero errors? Software organizations have done just that. In this article, I list small steps you can take that will lead your company toward similar results based on my 15 years of process improvement experience.
and use it to pilot the CMMI. As you work through that project, write the necessary standard operating instructions (SOI)/standard operating procedures (SOPs), as identified by the CMMI, and test them with that project. Once they are acceptable, publish them as an example of how your organization does business. Of course, these are living documents and as you mature, your processes must evolve with you.

**Perfect is the enemy of good enough.** If you are looking to produce perfect processes, you will never get there. Aim for the 80 percent solution. While that might seem pretty low, remember that each process has a feedback loop whereby improvements can easily and frequently be made. I know of no one who has ever gone to work thinking, “I want to do worse today than yesterday.” Most employees want to do a better job. The problem is that they do not always know how, but processes can give them a framework. Their experience and intuition will help fill in the details on how to improve.

**Jealousy is a great thing.** Do not let the lack of senior management support stop you. All you need is any manager to support CPI to get it going. Once you are making progress, others will see something is different with your manager: projects are being produced on time, on budget, and/or with greater quality. The other managers will become jealous and want to achieve the same success.

**Do not try to end world hunger.** Aim low and reach your target. If you try to fix your whole company, you will likely spend most of your time negotiating, selling, and/or compromising. It is better to fix your little niche and make others jealous (see above). Allow them to modify your processes to fit their needs. They will already have incentive to ensure they are successful (jealousy still reigns). If they fail, they will come back since they will become jealous over something else you are doing better than them (and reaping tangible rewards such as a bigger budget or additional people). They might even stumble onto a better process than yours – great! Ask to use it and make it work for you. Now you have a strong ally.

**Two heads are better than one.** Create a PIT encompassing each work unit in your area. As a PIT leader, you do not have the corner on good ideas. The more people you include (up to seven, plus or minus two), the better. However, you do not want just anyone. You want people who share your enthusiasm for process improvement and who see the big picture. If you have the wrong team members, it can be detrimental because you will spend 80 percent of your time educating 20 percent of them.

- **Every team needs cheerleaders.** If you document/improve all processes but no one knows about them, you have accomplished nothing. Find the opinion leaders in each work area and get them involved. If they are not on the PIT, try to include them on the occasional work group or have them write an article for the PIT newsletter. That newsletter can be another good cheerleader. It is your first opportunity to provide training snippets on new processes as well as keeping everyone informed of your current CPI status.
- **Fail and get over it.** As humans we are imperfect. Do not worry about failure. The only failure is one where you learn nothing. If you are unsuccessful and learn from it then it was a great learning experience, not a failure because you now know at least one way not to do it.
- **Start with the obvious.** The CMMI-ACQ has a lot of information about what your acquisition program should contain. It does not tell you how to do it but there is plenty of what. Do not wait until you have the how to get started. Take the what (i.e., CMMI) and turn it into a policy statement (SOI). Then, when it is time to create the how (SOP), people will know which how to develop. You will have already added some structure to your process improvement effort.
- **Keep focused.** When writing an SOI, do not delve into how people should do something. You want to focus on what they are to do and, on occasion, why. You can even describe a little of who or when. Once an SOP is created then it is time to describe how to do the job. These SOIs/SOPs should not be written for a three-year-old, but they also should not be written for a brain surgeon (unless it is an SOP on brain surgery). You should rarely include any why material in an SOP. If the worker does not know why they are doing their job, they have bigger issues. SOPs should be written by those already doing the job.
- **We don’t need no stinkin’ tools.** Just as everyone wants instant gratification, we also want a super tool to make our jobs easier, thus solving all of our problems. Come back to reality. That tool does not exist. I have found that if you buy a tool to solve your problems, you are more likely to get a failed CPI effort – and be poorer to boot. Because you do not have a repeatable process, the tool only lets you make mistakes faster, easier, and with greater impact. Of course, this frustrates people and they will quit using the tool. They will not realize it was the lack of process that caused the problems, not the tool. First, create a process and then introduce a tool to help people perform the process faster, cheaper, and better.

**Sometimes status quo is good.** Remember, people want to do their jobs better – they just do not want to change to do that. The mere act of documenting your current (probably flawed) processes is a huge improvement over undocumented processes. At least now you could repeat the process twice in a row. It is better to get the early buy-in than try to perfect the process too quickly. There will be plenty of opportunity to improve the process as people use it.

**Sometimes status quo is bad.** Hopefully you will never hear we do it this way because it is how we have always done it. However, someone is thinking...
it. My experience is that if people do not know why they are doing something, they are also ripe for the suggestion that there might be a better way, especially if it means less work. Many of the always done it this way processes can be reduced in effort by 50 percent or more. Often, some work products are used by no one. If a product has no customer (user), eliminate it. You will earn many new friends. If there was a hidden customer, they will eventually figure out something changed and come to you to explain why they need what you eliminated. Then you will know why it is needed.

- **Keep it short.** We keep SOIs to no more than three pages. Most are one to one-and-a-half pages, with the shortest being two paragraphs. SOPs are longer, but we still try to keep them to about four pages. If attachments are added, we do not count those against the four-page goal. A short document will get read, but a long one will not. Our plan is to write 100 short documents instead of one all-encompassing volume.

- **Do not get hung up on training.** Some people feel they need training on everything. At some level, I agree. However, it is just as bad to do too much training as not enough. No one needs training on our SOIs. Even most SOPs are written so that anyone sufficiently educated could pick up an SOP and determine how to perform its task. Use screen captures, pictures, and flowcharts — some people like words, some need pictures. Cater to both but keep it short, and provide training as needed or requested.

- **A hyperlink is your friend.** Ample hyperlinking avoids redundancy and inaccuracy. For instance, we have an SOI describing acronyms and definitions. All acronyms and definitions used in our SOIs/SOPs are included here. We then name the definition as a bookmark and hyperlink upon its first use in each document. That way we ensure the proper definition is used and we do not have to spell it out, which keeps our documents shorter.

- **Procrastination is your enemy.** There is no bad place to start a CPI effort except to not start at all. I do not know how many times I have been asked how to start a CPI effort. I answer, “It doesn’t matter.” Start where you feel most comfortable, with what causes the most headaches, with what will give the best return on investment, or you can use any other criteria. As Nike said, *just do it.*

- **I think I can, I think I can.** The Little Engine That Could ran uphill for a long time. It was about out of steam when it crested the hill and things became easier. So it is with CPI. You will face an uphill battle for at least six months — and probably more. However, at some point (that point will be different for each organization) you will crest the hill and gain momentum. At that point, no one can stop your CPI effort. It will be institutionalized and no longer dependent on individuals, becoming an integral part of your organization’s business practices. As long as you have steam, you must keep chugging uphill. Set your sights just over the crest and you will get there.

- **This is not three-card monte. Pick a model, any model.** There are many process models from which to choose (CMM, CMMI, International Organization for Standardization [ISO] 9000, TQM, Lean, Six Sigma, Lean Six Sigma, etc.). Which should you use? When you are getting started, it does not matter. Just pick one and go. Any improvement is better than none. You may even choose bits and pieces of several models. Having said that, I believe the CMM and CMMI models are the most comprehensive and take you farther than the others. For instance, ISO 9000 takes you to about a CMMI Level 2. The Lean and Six Sigma models require you to document your process first, so you can determine just how much it has improved. Since most organizations just starting CPI do not have documented processes, it seems the CMM/CMMI might be best for starting because they provide guidance on what should be in your key processes. As your processes mature, you will likely incorporate other models into your CPI effort to speed your progress or improve the quality. Use whatever works for you.

- **Do not reinvent the wheel.** Reuse is your friend. Build on others’ successes. Learn from them. Never embrace not invented here syndrome. The Software Engineering Institute already developed all the tools you need to start making significant leaps in the quality of your processes. Their CMM and CMMI models describe every characteristic your organization should exhibit at various levels of process maturity. Use the models — they work. They will give you quality processes leading to quality products.

From what I have seen, most failed CPI efforts could not figure out where to begin, lost steam before starting, could not get any management support (usually tried at too high a level), focused too much on tools versus processes, could not find a quick fix and quit, or tried to solve world hunger and gave up.

Based on my 15 years in process improvement, I suspect that if you follow these suggestions, sticking with it at least two years, you will be successful in your CPI effort.

If you have CPI lessons learned, I would enjoy hearing them.

Urgent Reader Request!

Have we helped? How?

CROSSTALK has been there for you for almost twenty years, and now we are asking that you be there for CROSSTALK. As a free publication, your comments are the lifeblood of our existence. Has the information provided in our publication ever helped you save time or money? Have you benefitted in other ways? If so, we want to hear about it.

Our goal has always been to inform and educate you — our readers — on software engineering best practices, processes, policies and other technologies. If we have succeeded in this goal, let us know “how, where, when, and why.” Your comments will help CROSSTALK continue to bring you the news and information you’ve come to expect.

Send your stories of success to crosstalk.publisher@hill.af.mil, or go to www.stsc.hill.af.mil/crosstalk.

We will feature your comments in our 20th anniversary issue this August.

Thank You!

Articles ... and metrics
helped me save $33.5 million
on government programs.

The Use and Limitations of Static-Analysis Tools to Improve Software Quality

Dr. Paul Anderson
GrammaTech, Inc.

Advanced static-analysis tools have been found to be effective at finding defects that jeopardize system safety and security. This article describes how these tools work and outlines their limitations. They are best used in combination with traditional dynamic testing techniques, and can even reduce the cost to create and manage test cases for stringent run-time coverage.

Static analysis has commonly been known as a technique for finding violations of superficial stylistic programming rules, and for alerting programmers to typing discrepancies in type-unsafe languages. The latest static-analysis tools go far beyond this, and are capable of finding serious errors in programs such as null-pointer de-references, buffer overruns, race conditions, resource leaks, and other errors. They can do so without requiring additional input from the users, and without requiring changes to development processes or practices. Actionable results are produced quickly with a low level of false positives. These static-analysis tools are not a silver bullet, however, because they can never prove that a program is completely free of flaws. The following is a description of how static-analysis tools work, followed by a discussion of how they can be used to complement traditional testing.

How Static Analysis Finds Flaws

The first thing a static analysis tool must do is identify the code to be analyzed. The source files that must be compiled to create a program may be scattered across many directories, and may be mixed in with other source code that is not used for that program. Static analysis tools operate much like compilers so they must be able to identify exactly which source files contribute and should ignore those that do not. The scripts or build system that builds the executable obviously know which files to use, so the best static analysis tools can extract this information by reading those scripts directly or by observing the build system in action. This way the tool gets to see not only the source files but also which compiler is being used and any command-line flags that were passed in. The parser that the static analysis tool uses must interpret the source code in the same way that the real compiler does. It does this by modeling how the real compiler works as closely as possible. The command-line flags are an essential input to that.

As the build system progresses, each invocation of the compiler is used to create a whole program model of the program. This model consists of a set of abstract representations of the source, and is similar to what a compiler might generate as an intermediate representation. It includes the control-flow graph, the call graph, and information about symbols such as variables and type names.

Once the model has been created, the analysis performs a symbolic execution on it. This can be thought of as a simulation of a real execution. Whereas a real execution would use concrete values in variables, the symbolic execution uses abstract values instead. This execution explores paths and, as it proceeds, if any anomalies are observed, they are reported as warnings. This approach is based on abstract interpretation [1] and model checking [2].

The analysis is path-sensitive, which means that it can compute properties of individual paths through the program. This is important because it means that when a warning is reported, the tool can tell the user the path along which execution must proceed in order for the flaw to be manifest. Tools also usually indicate the points along that path where relevant transformations occur and conditions on the data values that must hold. These help users understand the result and how to correct the problem should it be confirmed.

Once a set of warnings have been issued, these tools offer features to help the user manage the results, including allowing the user to manually label individual warnings. Warnings that correspond to real flaws can be labeled as true positives. Warnings that are false alarms can be labeled as false positives. Warnings that are technically true positives but which are benign can be labeled as don’t care. Most tools offer features that allow the user to suppress reporting of such warnings in subsequent analyses.

Limitations of Static Analysis

In order to understand the limitations of the techniques that these tools use, it is important to understand the metrics used to assess their performance.

The three metrics usually operate in opposition to each other. It is easy to create a tool that has perfect precision and excellent performance – one that
reports no lines contain flaws will satisfy because it reports no false positives. Similarly, it is easy to create a tool with perfect recall and excellent performance – one that reports that all lines have errors will answer because it reports no false negatives. Clearly, however, neither tool is of any use whatsoever.

Finally, it is at least theoretically possible to write an analyzer that would have excellent precision and excellent recall given enough time and access to enough processing power. Whether such a tool would be as useless as the previous two example tools is debatable and would depend on just how much time it would take. What is clear is that no such tools currently exist and to create them would be very difficult.

As a result, all tools occupy a middle ground around a sweet spot that developers find most useful. Developers expect analyses to complete in time roughly proportional to the size of their code base and within hours rather than days. Tools that take longer simply do not get used because they take too long. Low precision means more false positives, which has an insidious effect on users. As precision goes down, even true positive warnings are more likely to be erroneously judged as false positives because the users lose trust in the tool.

For most classes of flaws, precision less than 80 percent is unacceptable. For more serious flaws, however, precision as low as five percent may be acceptable if the code is to be deployed in very risky environments. It is difficult to quantify acceptable values for recall as it is impossible to measure accurately in practice, but clearly users would not bother using these tools at all if they did not find serious flaws that escape detection by other means.

Each of these constraints introduces its own set of limitations, however they are all interrelated. The reasons that lead to low recall are explained in more detail in the following sections.

Path Limitations
As mentioned earlier, there are no true positives or false negatives, and it is impossible to measure precisely in practice, but clearly users would not bother using these tools if they did not find serious flaws that escape detection by other means.

Each of these constraints introduces its own set of limitations, however they are all interrelated. The reasons that lead to low recall are explained in more detail in the following sections.

Path Limitations
As mentioned earlier, these analyses are path sensitive. This improves both recall and precision and is probably the key aspect of these products that makes them most useful. A full exploration of all paths through the program would be very expensive. If there are a large number of intraprocedural paths through that procedure, this can be as many as 2^n in practice, this is fewer because some branches are correlated, and the asymptotic behavior remains. If procedure calls and returns are taken into account, the number of paths is doubly exponential, and if loops are taken into account then the number of paths is unbounded. Clearly it is not possible for a tool to explore all of these paths. The tools restrict their exploration in two ways. First, loops are handled by exploring a small fixed number of iterations; often, the first time around the loop is singled out as special, and all other iterations are considered en masse and represented by an approximation. Second, not all paths are explored. It is typical for an analysis to place an upper bound on the number of paths explored in a particular procedure or on the amount of time available, and a selection of those remaining paths are explored.

If asynchronous paths can occur (such as those caused by interrupts or exceptions) or if the program uses concurrency, then the number of possible paths to consider increases further. Many tools simply ignore the possibilities.

Abstract Domain
As previously mentioned, these tools work by exploring paths and looking for anomalies in the abstract state of the program. The appeal of the symbolic execution is that each abstract state represents potentially many possible concrete states. For example, given an 8-bit variable x, there are 2^8 possible concrete values: 0, 1, …, 255. The symbolic execution, however, might represent the value as two abstract states: x=0, and x>0. So where a concrete execution has 256 states to explore, the symbolic execution has only two.

As such, the expressivity of this abstract domain is an important factor that determines the effectiveness of the analysis. Again, there is a trade-off here: better precision and recall can be achieved by more sophisticated abstract domains, but more resources will then be required to complete an analysis. Values in the abstract domain are equations that represent constraints on values, i.e., x=0, or x>10. As the analysis progresses, a constraint solver is used to combine and simplify these equations. A key characteristic of these abstract domains is that there is a special value, usually named bottom, which indicates that the analysis knows no useful information about the actual value. Bottom is the abstract value that corresponds to all possible concrete values. Reaching bottom is impossible to avoid for any non-trivial abstraction in general as this would require solving the halting problem. Once bottom is reached, the analysis has a choice of treating it as a potentially dangerous value, which would increase recall, or as a probably safe value, which would increase precision. Most tools opt for the latter as the former also has the effect of decreasing precision enormously.

If there are program constructs that step outside the bounds of what can be expressed in the abstract domain, this causes the analysis to lose track of variables and their relationships. For example, an abstract domain that allows the expression of affine relationships between no more than two variables admits expressions such as x=2y. However, something such as x=y+z is out of bounds because it involves three variables and the analysis would be forced to conclude x=bottom instead.

The consequence of this is the abstract domain that a tool uses determines a great deal about the kind of flaws that it is capable of detecting. For example, if the tool uses an abstract domain of affine relations between two variables, then it may fail to find flaws that depend on three variables.

Similarly, most tools choose a domain that allows them to reason about the values of integers and addresses but not floating-point values, so they will fail to find flaws in floating-point arithmetic (such as divide by zero).

**Missing Source Code**

If the source code to a part of a program is not available, as is almost always the case because of operating system and third-party libraries, or if the code is written in a language not recognized by the analysis tool, then the analysis must make some assumptions about how that missing code operates. Take, for example, a call to a function in a third-party library that takes a single pointer-type parameter and returns an integer. In the absence of any other information, most analyses will assume that the function does nothing and returns an unknown value. This clearly is not realistic, but it is not practical to do better in general. The function may de-reference its pointer parameter, it may read or write any global variable that is in scope, it may return an integer from a particular range, or it may even abort execution. If the analysis knew this, it would have better precision and recall but it is forced to make the simple assumption unless told otherwise.

There are two approaches around this. First, if source is not available but object code is, then the analysis could be extended into the object code. This is a highly attractive solution but no products are available yet. The technological basis for such a tool exists, however [3], and it is expected that products capable of analyzing object code as well as C/C++ will appear.

A second approach to the problem is to specify stubs, or models, that summarize key aspects of the missing source code. The popular analysis tools provide models for commonly used libraries such as the C library. These models only have to approximate the behavior of the code. Users can, of course, write these themselves for their own libraries but it can be a tricky and time-consuming effort.

**Out of Scope**

There are, of course, entire classes of flaws that static analysis is unlikely ever to be able to detect. Static analysis excels at finding places where the fundamental rules of the language are being violated such as buffer overruns, or where commonly used libraries are being used incorrectly, or where there are inconsistencies in the code that indicate misunderstanding. If the code does the wrong thing for some other reason, but does not then terminate abnormally, then static analysis is unlikely to be able to help because it is unable to divine the intent of the author. For example, if a function is intended to sort in ascending order, but perfectly sorts in descending order instead, then static analysis will not help much. This kind of functionality testing is what traditional dynamic testing is good for.

**Static Analysis and Testing**

Static analysis should never be seriously considered as a replacement for traditional dynamic testing activities. Rather, it should be thought of as a way of amplifying the software assurance effort. The cheapest bug to find is the one that gets found earliest, and as static analysis can be used very early in the development cycle, its use can reduce the cost of development and liberate resources for use elsewhere. This is the traditional view of how static analysis can reduce testing costs. However, there is a second way in which the use of static analysis can reduce the cost of testing: it makes it easier to achieve full coverage.

One measure of the effectiveness of a test suite is how well it exercises or covers the code being tested. There are many different kinds of coverage. Statement coverage is the most common, but for riskier code more stringent forms are often required. Decision coverage is a superset of statement coverage, and requires that all branches in the control flow of the program are taken. In DO-178B, a development standard for flight software [4], the riskiest code is required to be tested with 100 percent modified condition/decision coverage (MCDC). This means that a test suite must be chosen such that all sub-expressions in all conditionals are evaluated to both true and false. Table 1 illustrates how many different test cases are needed for each to achieve coverage. For the code sample on the left, the values required of the boolean variables a, b, and c to achieve each form of coverage is shown on the right.

Achieving full coverage, even for statement coverage, can be very time consuming. The engineer creating the test case must figure out what inputs must be given to drive the program to each statement. What can make it very frustrating is if it is fundamentally impossible to do so, but this may not be
apparent simply by looking at the code. If the program contains unreachable code, then statement coverage is impossible. If it contains redundant conditions (those that are either always true or always false), then MCDC is impossible. Developers can spend hours trying to refine a test case before it is evident that their efforts are pointless.

If the unreachable code or redundant conditions can be brought to the attention of the tester early, then they do not need to waste time in a futile attempt to achieve the impossible. This is what static analysis can do easily and efficiently. Figure 1 shows an example of a report from CodeSonar illustrating a redundant condition in a sample of code taken from an open-source application. The variable rest, an unaliased integer, must be at least three by line 12. The decrement on that line means it is at least two, so the condition will always be true. The following line is also redundant and shown in a different report.

In this example, all the components of the code relevant to the redundancy are in close proximity so it is likely that a reviewer would have spotted this during a manual review. It would not have been so easy to spot if the code were more complex. If the code had spanned several pages, or if relevant parts had been embedded in function calls or macro invocations, then it would have been difficult to spot. Static analysis is not sensitive to superficial aspects of the code such as its layout, so it would not have been confused.

These kinds of redundancies correlate well with genuine flaws as well; for example, consider the example in Figure 2. This was distilled from a genuine flaw found in a widely used open-source program, and is a redundant condition warning where the tool has deduced that the true branch of the conditional will never be taken. The reason why it concluded so is shown to the left. The first operand to the bitwise AND (the & symbol) is either zero or one as this is the value of the negation operator (the ! symbol). This is what is represented by $temp2. The constant MASK has the value 16. The result of the AND expressions $1 & 16 and 0 $1 & 16 are both zero, so the conditional expression is guaranteed to be zero.

The programmer who wrote this code probably misunderstood the precedence of the operators in the conditional expression and assumed that the innermost operator had higher precedence. If so, then a correction would be to place parentheses around the inner expression. This is a potentially dangerous flaw as it means that the error condition would not be detected, which could result in unpredictable behavior.

**When to Use Static Analysis Tools**

The best time to use advanced static analysis tools is early in the development cycle. In Holzmann’s 10 rules for safety-critical development [5], the most far-reaching rule states that these tools should be used throughout the development process. As well as reducing the cost of development by finding flaws earlier and reducing testing effort, early adoption exerts a force on programmers to write code that is more amenable to analysis, thereby increasing the probability that the tool will find errors. Care should be taken, however, to avoid a risk compensation phenomenon, where programmers use less care because they assume that the static analysis tool will find their mistakes.

If adopted late in the development cycle, static analysis may issue a large number of warnings. The best value is gained if these are all dealt with, either by fixing the code, marking them as false positives, or labeling them as don’t care if they are believed to be benign. However, if scheduling time to sift through these is not feasible, then an alternative strategy is to operate in a differential mode, where programmers are only told about new warnings. This way they are alerted to flaws in code that they are working with while it remains fresh in their minds.

**Conclusion**

Advanced static analysis tools offer much to help improve the quality of software. The best tools are easy to integrate into the development cycle, and can yield high-quality results quickly without requiring additional engineering effort. They can be used not just for finding flaws, but also to guide testing activities. They use sophisticated symbolic execution techniques for which engineering trade-offs have been made so that they can generate useful results in a reasonable time. As such, they inevitably have both false positives and false negatives, and so should never be considered a replacement for traditional testing techniques.

Automated Combinatorial Test Methods – Beyond Pairwise Testing

D. Richard Kuhn and Dr. Raghu Kacker
National Institute of Standards and Technology

Pairwise testing has become a popular approach to software quality assurance because it often provides effective error detection at low cost. However, pairwise (2-way) coverage is not sufficient for assurance of mission-critical software. Combinatorial testing beyond pairwise is rarely used because good algorithms have not been available for complex combinations such as 3-way, 4-way, or more. In addition, significantly more tests are required for combinations beyond pairwise testing, and testers must determine expected results for each set of inputs. This article introduces new tools for automating the production of complete test cases covering up to 6-way combinations.

Many testers are familiar with the most basic form of combinatorial testing – all pairs or pairwise testing, in which all possible pairs of parameter values are covered by at least one test [1, 2]. Pairwise testing uses specially constructed test sets that guarantee testing every parameter value interacting with every other parameter value at least once. For example, suppose we had an application that is intended to run on a variety of platforms comprised of five components: an operating system (Windows XP, Apple OS X, Red Hat Linux), a browser (Internet Explorer, Firefox), protocol stack (IPv4, IPv6), a processor (Intel, AMD), and a database (MySQL, Sybase, Oracle), a total of 3 x 2 x 2 x 2 x 2 = 48 possible platforms. With only 10 tests, as shown in Figure 1, it is possible to test every component interacting with every other component at least once, i.e., all possible pairs of platform components. The effectiveness of pairwise testing is based on the observation that software faults often involve interactions between parameters. While some bugs can be detected with a single parameter value, the toughest bugs often can only be detected when multiple conditions are true simultaneously. For example, a router may be observed to fail only for the User Datagram Protocol (UDP) when packet rate exceeds 1.3 million packets per second – a 2-way interaction between protocol type and packet rate. An even more difficult bug might be one which is detected only for UDP when packet volume exceeds 1.3 million packets per second and packet chaining is used – a 3-way interaction between protocol type, packet rate, and chaining option.

Unfortunately, only a handful of tools can generate more complex combinations, such as 3-way, 4-way, or more (we refer to the number of variables in combinations as the combinatorial interaction strength, or simply, interaction strength, e.g., a 4-way combination has 4 variables and thus its interaction strength is 4). The few tools that do generate tests with interaction strengths higher than 2-way may require several days to generate tests [3] because the generation process is mathematically complex. Pairwise testing, i.e. testing 2-way combinations, has come to be accepted as the standard approach to combinatorial testing because it is computationally tractable and can effectively detect many faults. For example, pairwise testing could detect 70 percent to more than 90 percent of software faults for the applications studied in [4].

But if pairwise testing can detect 90 percent of bugs, what interaction strength is needed to detect 100 percent? Surprisingly, we found no evidence that this question had been studied when the National Institute of Standards and Technology (NIST) began investigating software faults in 1996. Results showed that across a variety of domains, all failures could be triggered by a maximum of 4-way to 6-way interactions [5]. As shown in Figure 2, the detection rate increases rapidly with interaction strength. With the NASA application, for example, 67 percent of the failures were triggered by only a single parameter value, 93 percent by 2-way combinations, and 98 percent by 3-way combinations. The detection rate curves for the other applications are similar, reaching 100 percent detection with 4-way to 6-way interactions. That is, six or fewer variables were involved in all failures for the applications studied, so 6-way testing could, in theory, detect all of the failures. While not conclusive, these results suggest that combinatorial testing that exercises high strength interaction combinations can be an effective approach to high-integrity software assurance.

Applying combinatorial testing to real-world software presents a number of challenges. For one of the best algorithms, the number of tests needed for combinatorial coverage of \( n \) parameters with \( v \) values each is proportional to \( v^i \log n \), where \( i \) is the interaction strength [3]. Unit testing of a small module with 12 parameters required only a few dozen tests for 2-way combinations, but approximately 12,000 for 6-way combinations [6]. But a large number of test cases will not be a barrier if they can be produced with little human intervention, thus reducing cost. To apply combinatorial testing, it is necessary to find a set of test inputs that covers all \( t \)-way combinations of parameter values, and to match up each set of inputs with the expected output for these input values.

</table>
These are both difficult problems, but they can now be solved with new algorithms on currently available hardware. We explain these two steps followed by a small but complete illustrative example.

Computing T-Way Combinations of Input Values Using FireEye

The first step in combinatorial testing is to find a set of tests that will cover all t-way combinations of parameter values for the desired combinatorial interaction strength t. This collection of tests is known as a covering array. The covering array specifies test data where each row of the array can be regarded as a set of parameter values for an individual test. Collectively, the rows of the array cover all t-way combinations of parameter values. An example is given in Figure 3, which shows a 3-way covering array for 10 variables with two values each. The interesting property of this array is that any three columns contain all eight possible values for three binary variables. For example, taking columns F, G, and H, we can see that all eight possible 3-way combinations (000, 001, 010, 011, 100, 101, 110, 111) occur somewhere in the rows of the three columns. In fact, this is true for any three columns. Collectively, therefore, this set of tests will exercise all 3-way combinations of input values in only 13 tests, as compared with 1,024 for exhaustive coverage. Similar arrays can be generated to cover up to all 6-way combinations. A non-commercial research tool called FireEye [3], developed by NIST and the University of Texas at Arlington, makes this possible with much greater efficiency than previous tools. For example, a commercial tool required 5,400 seconds to produce a less-optimal test set than FireEye generated in 4.2 seconds.

Matching Combinatorial Inputs With Expected Outputs Using Nu Symbolic Model Verifier (SMV)

The second step in combinatorial test development is to determine what output should be produced by the system under test for each set of input parameter values, often referred to as the oracle problem in testing. The conventional approach to this problem is human intervention to design tests and assign expected results or, in some cases, to use a reference implementation that is known to be correct (for example, in checking conformance of various vendor products to a protocol standard). Because combinatorial testing can require a large number of tests, an automated method is needed for determining the expected results for each set of input data. To solve this problem, we use the open-source NuSMV model checker [7] (an enhanced version of the well-known SMV model checker [7]). Conceptually, the model checker can be viewed as exploring all states of a system model to determine if a property claimed in a specification statement is true. What makes a model checker particularly valuable is that if the claim is false, the model checker not only reports this, but also provides a counterexample showing how the claim can be shown false. As will be seen in the illustrative example, this gives us the ability to match every set of input test data with the result that the system should produce for that input data. Figure 4 outlines the process.

The model checker thus automates the work that normally must be done by a human tester – determining what the correct output should be for each set of input data. Other approaches to determining the correct output for each test can also be used. For example, in some cases we can run a model checker in simulation mode, producing expected results directly rather than through a counterexample, but the approach illustrated in this article is more general, and can be applied to non-deterministic systems or used with mutation-based methods in addition to combinatorial testing [8]. The method chosen for resolving the oracle problem depends on the problem at hand, but model checking can be effective in testing protocols, access control, or other applications where there is a state machine, unified modeling language state chart, or other formal model available.

Illustrative Example

Here we present a small example of an access control system. The rules of the system are a simplified multi-level security system, followed by a step-by-step construction of tests using an automated process. Each subject (user) has a clearance level n, and each file has a classification level f. For example, in some cases we can run a model checker in simulation mode, producing expected results directly rather than through a counterexample, but the approach illustrated in this article is more general, and can be applied to non-deterministic systems or used with mutation-based methods in addition to combinatorial testing [8]. The method chosen for resolving the oracle problem depends on the problem at hand, but model checking can be effective in testing protocols, access control, or other applications where there is a state machine, unified modeling language state chart, or other formal model available.

Figure 2: Error Detection Rates for Interaction Strengths 1 to 6

Figure 3: 3-way Covering Array for 10 Parameters With Two Values Each
Levels are given as 0, 1, or 2, which could represent levels such as Confidential, Secret, and Top Secret. A user \( u \) can read a file if \( u_l \geq f_l \) (the no read up rule), or write to a file if \( f_l \geq u_l \) (the no write down rule).

Thus, a pseudo-code representation of the access control policy is:

\[
\text{if } u_l \geq f_l \land \text{act} = \text{rd} \text{ then GRANT;}
\]
\[
\text{else if } f_l \geq u_l \land \text{act} = \text{wr} \text{ then GRANT; else DENY;}
\]

Tests produced will check that these rules are correctly implemented in a system.

**System Model**

This system is easily modeled in the language of the NuSMV model checker as a simple two-state finite state machine. Other tools could be used, but we illustrate the test production procedure using NuSMV because it is among the most widely used model checkers and is freely available. Our approach is to model the system as a simple state machine, then use NuSMV to evaluate the model and post-process the results into complete test cases.

Figure 5 shows the system model defined in SMV. The \( \text{START} \) state initializes the system (line 8), with the rule noted previously used to evaluate access as either \( \text{GRANT} \) or \( \text{DENY} \) (lines 9-13). For example, line 10 represents the first line of the pseudo-code example: in the current state, (always \( \text{START} \) for this simple model), if \( u_l \geq f_l \) then the next state is \( \text{GRANT} \).

Each line of the case statement is examined sequentially, as in a conventional programming language. Line 12 implements the \( \text{else DENY} \) rule, since the predicate \( j \) is always true. SPEC clauses given at the end of the model define statements that are to be proven or disproven by the model checker. The SPEC statements in Figure 5 duplicate the access control rules as temporal logic statements and are, thus, provable. In the following sections, we illustrate how to combine them with input data values to generate complete tests with expected results.

In SMV, specifications of the form \( \text{AG} (\text{predicate 1}) \rightarrow \text{AX} (\text{predicate 2}) \) indicate essentially that for all paths (the \( A \) in AG) for all states globally (the \( G \), if predicate 1 holds then \( \rightarrow \) for all paths, in the next state (the \( X \) in AX) predicate 2 will hold. SMV checks the properties in the SPEC statements and shows that they match the access control rules as implemented in the finite state machine, as expected. Once the model is correct and SPEC claims have been shown valid for the model, counterexamples can be produced that will be turned into test cases.

**Generating Covering Array**

We will compute covering arrays that give all \( t \)-way combinations, with degree of interaction coverage two for this example. If we had a larger number of parameters, we would produce test configurations that cover all 3-way, 4-way, etc., combinations. (With only three parameters, 3-way interaction would be equivalent to exhaustive testing, so we use 2-way combinations for illustration purposes.) The first step is to define the parameters (using the graphical
user interface if desired) and their values in a system definition file that will be used as input to the covering array generator FireEye with the following format: After the system definition file is saved, we run FireEye, in this case specifying 2-way interactions. FireEye produces the output shown in Figure 6.

Each test configuration defines a set of values for the input parameters $u_l$, $f_l$, and $act$. The complete test set ensures that all 2-way combinations of parameter values have been covered.

### Model Claims With Covering Array Values Inserted

The next step is to assign values from the covering array to parameters used in the model. For each test, we write a claim that the expected result will not occur. The model checker determines combinations that would disprove these claims, outputting these as counterexamples. Each counterexample can then be converted to a test with known expected result. For example, for Test 1 the parameter values are:

$$u_l = 0 \& f_l = 0 \& act = rd$$

For each of the nine configurations in the covering array (Figure 7), we create a SPEC claim of the form: $SPEC\ AG(covering\ array\ values) \rightarrow AX(\!access = result)$. This process is repeated for each possible result, in this case either GRANT or DENY, so we have nine claims for each of the two results. The model checker is able to determine, using the model defined previously, which result is the correct one for each set of input values, producing a total of nine tests.

**Excerpt:**

```plaintext
SPEC AG((u_l = 0 & f_l = 0 & act = rd) -> AX !(access = GRANT));
SPEC AG((u_l = 0 & f_l = 1 & act = wr) -> AX !(access = GRANT));
SPEC AG((u_l = 0 & f_l = 2 & act = rd) -> AX !(access = GRANT));
```

**Generating Counterexamples With Model Checker**

NuSMV produces counterexamples where the input values would disprove the claims specified in the previous section. Each of these counterexamples is, thus, a set of test data that would have the expected result of GRANT or DENY. For each SPEC claim, if this set of values cannot in fact lead to the particular result, the model checker indicates that this is true. For example, for the configuration below, the claim that access will not be granted is true, because the user’s clearance level ($u_l = 0$) is below the file’s level ($f_l = 2$):  

```
SPEC AG((u_l = 0 & f_l = 2 & act = rd) -> AX!(access = GRANT)) is true
```

If the claim is false, the model checker indicates this and provides a trace of parameter input values and states that will prove it is false. In effect, this is a complete test case, i.e., a set of parameter values and an expected result. It is then simple to map these values into complete test cases in the syntax needed for the system under test. An excerpt from NuSMV output is shown in Figure 8.

The model checker finds that six of the input parameter configurations produce a result of GRANT and three produce a DENY result, so at the completion of this step we have successfully matched up each input parameter configuration with the result that should be produced by the system under test.

At first, the method previously described may seem backward. Instead of negating each possible result, why not simply produce tests from model checker output such as specification AG (((u_l = 0 & f_l = 2) & act = rd) -> AX (access = DENY)) is true? Such a procedure would work fine for this simple example, but more sophisticated testing may require more information. Note that if the claim is true, the model checker simply reports the fact while if it is false, a trace of inputs and internal states is produced to show how the claim fails. Some testing may require information on internal states or variable values, and the previous procedure provides this information.

### Shell Script Post-Processing to Produce Complete Tests

The last step is to use a post-processing tool that reads the output of the model checker and generates a set of test inputs with expected results. The post-processor strips out the parameter names and values, giving tests that can be applied to the system under test. Simple scripts are then used to convert the test cases into input for a suitable test harness. The tests produced are shown in Figure 9 (see next page).

### Conclusion

While tests for this trivial example could easily have been constructed manually, the procedures introduced in this tutorial can – and have – been used to produce tens of thousands of complete test cases in a few minutes once the SMV model...
has been defined for the system under test. The methods in this article still require human intervention and engineering judgment to define a formal model of the system under test and for determining appropriate abstractions and equivalence classes for input parameters. But by automating test generation we can provide much more thorough testing than is possible with most conventional methods. In addition, the testing has a sound empirical basis in the observation that software failures have been shown to be caused by the interaction of relatively few variables. By testing all variable interactions to an appropriate strength, we can provide stronger assurance for critical software.

### About the Authors

**D. Richard Kuhn** is a computer scientist in the computer security division of the National Institute of Standards and Technology (NIST). His primary technical interests are in information security, software assurance, and empirical studies of software failure. He co-developed the role based access control model (RBAC) used throughout industry, and led the effort to establish RBAC as an American National Standards Institute standard. Kuhn has a masters degree in computer science from the University of Maryland, College Park, and a bachelors and master of business administration from William & Mary.

**Yu Lei, Ph.D.**, is an assistant professor of computer science at the University of Texas, Arlington. He was a member of the Fujitsu Network Communications, Inc., technical staff from 1998 to 2001. Lei's research is in the area of automated software analysis, testing, and verification. His current research is supported by NIST. Lei has a bachelor's degree from Wuhan University, a master's degree from Chinese Academy of Sciences, and a doctorate from North Carolina State University.

**Raghu Kacker, Ph.D.**, is a mathematical statistician in the mathematical and computational sciences division of the NIST. His current interests include software testing, uncertainty in physical and virtual measurements, interlaboratory evaluations, and Bayesian uncertainty in measurement. Kacker received his doctorate in statistics from Iowa State University.

Software Quality Unpeeled

Dr. Jeffrey Voas
SAIC

The expression software quality has many interpretations and meanings. In this article, I do not attempt to select any one in particular, but instead help the reader see the underlying considerations that underscore software quality. Software quality is a lot more than standards, metrics, models, testing, etc. This article digs into the mystique behind this elusive area.

The term software quality has been one of the most overused, misused, and overloaded terms in software engineering. It is a generic term that suggests quality software but lacks general consensus on meaning. Attempts have been made to define it. The Institute for Electronics and Electrical Engineers (IEEE) Standard 729 defines it as:

… totality of features of a software product that bears on its ability to satisfy given needs and … composite characteristics of software that determine the degree to which the software in use will meet the expectations of the customer. [1]

However, this attempt and others are few, and not precise. In fact the second edition of the Encyclopedia of Software Engineering [2] does not have it listed as an entry; the encyclopedia skips straight from “Software Productivity Consortium” to “software reading.” And worse, books with software quality in the title never give a definition to it in their pages [3, 4].

If you review the past 20 years or so, you will find an abundance of other terms that have been employed as pseudo-synonyms for software quality. Examples include process improvement, software testing, quality management, the International Organization for Standardization 9001, software metrics, software reliability, quality modeling, configuration management, Capability Maturity Model® Integration, benchmarking, etc. In doing so, the term software quality has wound up representing a family of processes and ideas more than it represents good enough software. In short, software quality has become a culture and community more than a technical goal [5].

In this article, I will avoid the quicksand associated with trying to come up with a one-size-fits-all definition. Instead, I will expose how software quality is composed of various layers and, by peeling off different layers, it allows us to have a rational discussion between a typical software supplier and end user such that an agreement can be reached as to whether or not the software is good enough.

Certification

We will begin dissecting software quality by first looking at the multiple viewpoints behind the term certification. This will provide us with a look into our first layer.

“In some instances phantom users more heavily determine whether the software is fit for purpose than the traditional inputs. In short, it is environment that gives fit for purpose context.”

The term is often used to refer to certifying people skills. For example, the American Society for Quality (ASQ) has a host of certifications that individuals can attain in order to demonstrate competence in certain fields, e.g., they can become an ASQ Certified Software Quality Engineer. An individual can also become certified in specific commercial software packages, e.g., a Microsoft Certified Software Engineer.

For the purposes here, I employ a different perspective that comes from three schools of thought. The first school deals with certifying that a certain set of development, testing, or other processes applied during the pre-release phases of the life-cycle were satisfied. In doing so, you certify that the processes were followed and completed. (Demonstrating that they were applied correctly is a trickier issue.)

In the second school, you certify that the developed software meets the functional requirements; this can be accomplished via various types of testing or other analyses. For the third school, you can certify that the software itself is fit for purpose. This third school will be the most useful, and throughout this article, it will be considered software to be good enough if it is fit for purpose.

In this article, the term purpose suggests that two things are present: (1) executable software; and (2) an operating environment. An environment is a complex entity: It involves the set of inputs that the software will receive during execution, along with the probability that the events will occur [6]. This is referred to as the operational profile [6]. But it also involves the hardware that the software operates on, the operating system, available memory, disk space, drivers, and other background processes that are potentially competing for hardware resources, etc. These other factors are as much a part of the environment as are the traditional inputs; they have been termed invisible or phantom users.

In some instances phantom users more heavily determine whether the software is fit for purpose than the traditional inputs. In short, it is environment that gives fit for purpose context. By more completely defining and thus bounding the environment to include phantom users, we gain an advantage in that we can reduce the set of assumptions needed to predict whether the software is good enough. Understanding the distinction between traditional inputs and phantom users is one ingredient needed to argue that fit for purpose has been achieved.

Further, note that rarely will there be only one environment that software, and in particular general purpose software, will encounter during operation. That offers a key insight as to why general purpose software is not certified by independent laboratories; such laboratories could not be
omnipotent and could not know all of the potential target environments [7].

By revisiting the three schools of thought on certification, we discover eight ways to visualize software quality (See Table 1). Let us look at a couple.

In Table 1, scenario 2 represents a system that did not meet the requirements and was not developed according to the specified development procedures, but miraculously, the end result was software that was usable in the field. While this seems implausible, it is possible. Scenario 7 may seem like heresy to many in the community of software quality practitioners. It is not; it simply dispels the myth that requirements elicitation is far from a perfect science and that simply following common sense do’s and don’ts (as spelled out in a development process plan) guarantees good enough software [8].

Table 1: Views on Certification

<table>
<thead>
<tr>
<th>Scenario</th>
<th>Meets Requirements</th>
<th>Satisfies Development Processes</th>
<th>Fit for Purpose</th>
</tr>
</thead>

</tr>
</tbody>
</table>

Note that only four of these scenarios yield good enough software: 2, 4, 6, and 8. The other four provide a product that is not usable for its target environment and that brings us back to the discussion of why scoping the target environment as precisely as possible is an important piece of what software quality means.

In summary, fit for purpose is the nearest of the three certification schools of thought on the IEEE definitions for software quality. However, we cannot only rely on knowing the environment and expect to be justified in proclaiming we have achieved software quality. Let us explore other considerations.

### Three High-Level Attributes of Fit for Purpose

Most readers would probably be comfortable with labeling software as being of good quality if the software could ensure that (1) it produces accurate and reliable output, (2) it produces the needed output in a timely manner, and (3) it produces the output in a secure and private manner. These three criteria simply state that you get the right results at the right time at the correct level of security. These are the next three considerations that cannot be ignored and must incorporate into what software quality means.

While each of these is intuitive, none is precise enough. The family of attributes referred to as the ilities is a good starting point to help increase that precision [9]. This family includes behavioral characteristics such as reliability, performance, safety, security, availability, fault-tolerance, etc. (These attributes are also sometimes termed non-functional requirements.) Other family members such as dependability, survivability, sustainability, testability, interoperability, and scalability each require some degree of one or more of the first six attributes. So, for example, to have a dependable system, some level of reliable and fault-tolerant behavior is necessary. To have a survivable system, some amount of fault tolerance and availability is required, and so on. However, to simplify this discussion towards our goal of understanding the term software quality, we will focus only on the first six: reliability, performance, safety, security, availability, and fault-tolerance.

### “Ility” Oxymorons

Table 2 illustrates combinations of these six ilities. If we were to flesh this table out as we did in Table 1 we would have 64 rows; however, here we only show 14 combinations for brevity. (For the cells left empty, we are not considering the degree to which that attribute contributes to the quality of the software’s behavior.)

Let us look at a few of these categories and determine what they represent:

- **Category 1.** Suggests that the software is reliable, has good performance, does not trigger unsafe events to occur (e.g., in a transportation control system), has appropriate levels of security built in, has good availability and thus does not suffer from frequent failures resulting in downtime, and is resilient to internal failures (i.e., fault tolerant). Is all of this possible in a single software system?

- **Category 2.** Suggests that the software offers reliable behavior, but suffers from the likelihood of producing outputs that send the system that the software feeds inputs into an unsafe mode. This would represent a safety-critical system where hazardous fail-

</tbody>
</table>
ures are unacceptable; hazardous failures are categorized differently for such systems than failures that do not facilitate possible disastrous loss-of-life or loss-of-property consequences. (Note that software by itself is never unsafe; however software is often referred to as unsafe if it produces outputs to a system that put the system into an unsafe mode. Safety is a system property, not a software property.) A classic example of a reliable product that is unsafe is placing a functioning toaster into a bathtub of water with the cord still connected; the toaster is reliable, but it is not safe to go near.

- **Category 3.** Suggests that the software behaves so unrelentingly when executed that it cannot put the system into an unsafe mode. An example here would be that the software gets hung up in a loop and the safety functionality is never invoked.
- **Category 8.** Suggests safe but not secure software behavior. This is quite realistic for a safety-critical system with no security concerns. Note that the interesting aspect of this category is how safety and security are defined. Many people use these terms interchangeably, which is incorrect.
- **Category 11.** Suggests that the software behaves reliably and has good availability, but lacks adequate security precautions. Many systems suffer from this problem.
- **Category 12.** Suggests that the software behaves reliably, is extremely slow, but has adequate security. It makes one wonder if the system is so slow that it is effectively unusable, and thus secure, since it would take too long to break in.
- **Category 13.** Suggests high levels of security and high levels of performance. In certain situations that is plausible, however typically security kills performance and vice versa.
- **Category 14.** This is the easiest combination to achieve. Anyone can build a useless system.

The main point here is that the aforementioned high-level attributes (1) produce accurate and reliable output, (2) produce the needed output in a timely manner, and (3) produce the output in a secure and private manner are actually composed of the lower-level *ilities*. Another important point not to overlook is the fact that some of the *ilities* are not compatible with one another. An example of this can easily be found using fault tolerance and testability. A final important point is that some combinations of the *ilities* are simply counterintuitive, such as a system that is safe but unreliable.

One last thing to note: It is vital to get solid definitions for the *ilities* and to know which ones are quantifiable. For example, reliability and performance are quantifiable; security and safety are not. This makes it far easier to make statements such as *we have very high reliability but an unknown level of security.*

**The Shall Nots**

There is yet another layer in the notion of fit for use that deals with *negative* functional requirements. Think of a negative requirement as “the software shall *not* do X,” as opposed to a functional requirement stating that “the software *shall* do X.”

“For certain types of systems, particularly safety-critical systems, enumerating negative requirements is a necessity. And for software requiring security capabilities, security rules and policies are its equivalent to negative requirements.”

Negative requirements are far more difficult to elicit than regular requirements. Why? Because humans are not programmed to anticipate and enumerate all of the bad circumstances that can pop up and that we need protection against; we are instead programmed to think about the *good* things we want the software to do.

For certain types of systems, particularly safety-critical systems, enumerating negative requirements is a necessity. And for software requiring security capabilities, security rules and policies are its equivalent to negative requirements. For example, a negative security requirement could be that the software shall never open access to a particular channel unless it can be guaranteed that the information passing through the channel is moving between trusted entities. The difficulty in defining *shall not*s for security is that we cannot imagine all of the different forms of malicious attacks that are being invented on-the-fly and if we cannot imagine those attacks, we likely will not prevent them.

Before leaving the topic of negative functional requirements, it is worth mentioning an interesting relationship between them and the environment. So far, we have only mentioned traditional inputs and phantom users as players in the environment. Traditional inputs are those that the software expects to receive during operation. But there are two other types of inputs worth mentioning: malicious illegal and non-malicious illegal. A malicious illegal input is one that someone deliberately feeds into the software to attack a system, and a non-malicious illegal input is simply an input that the system designers do not want the software to accept but has no malicious intent. In both cases, filtering on either type of input can be useful to ensure that certain inputs do not become a part of the environment and in doing so ensure that negative functional requirements are enforced.

**Time**

The next layer in our quest for software quality is *time*. Software has fixed longevity; it can be expanded, as we learned from Y2K, but not indefinitely.

One of the easiest ways to explain why time fits here is to look at the situation where a software package operates correctly on Monday but does not operate correctly on Tuesday. Further, the software package was not modified between these days. (This is the classic problem that quickly carves down the number of freshman computer science majors.) Why has this problem occurred?

It all goes back to the importance of environment in the understanding of software quality. Earlier we defined the environment as inputs with probabilities of selection, hardware configurations, access to memory, operating systems, attached databases, and whether other background processes were over-indulging in resources, etc.

But what is not mentioned was *calendar time*. Environment is also a function of time. As time moves forward, other pieces of the environment change. And so while all effort and expense can be levied toward what we perceive is evidence supporting the claim that we have good enough software, we need to recog-
nize that even if we do have good enough software, it may be only for a short window of time. Thus, software quality is time-dependent, a bitter pill to swallow.

Cost
We cannot end this article without mentioning cost. The costs associated with software quality are exasperated by the un-family like behaviors of variousilities. Not only are there technical trade-offs discovered when trying to increase the degree to which one ility exists only to find that another is automatically decreased, but there is the financial trade-off quagmire concerning how to allocate financial resources between distinctilities. If you overspend on one, there may not be enough funds for another. And, as if the technical considerations are not hard enough when trying to define software quality, the financial considerations come aboard, making the problem worse.

Conclusion
In this article, a set of layers for what software quality means has been unpeeled. I have argued that a more useful perspective for what software quality represents starts from the notion of the software being fit for purpose, which requires:
1. Understanding the relationship between the functional requirements and the environment.
2. Understanding the three high-level attributes of software quality: the software: (a) produces accurate and reliable output, (b) produces the needed output in a timely manner, and (c) produces the output in a secure and private manner.
3. Understanding that the ilities afford the potential to have varying degrees of the high-level attributes.
4. Understanding that the shall-not functional requirements are often of equal importance to the functional requirements.
5. Understanding that there is a temporal component to software quality; software quality is not static or stagnant.
6. Understanding that the ilities offer technical incompatibilities as well as financial incompatibilities.
7. Understanding that the environment contains many more parameters such as the phantom users than is typically considered.
Thus, software quality, when viewed with these different considerations, becomes a far more interesting topic, and one that will continue to perplex us for decades to come.

Forecasting the Future

Welcome to the June issue of CROSSTalk – and I hope you didn't miss the Systems and Software Technology Conference (SSTC) conference in Las Vegas about a month ago. It was great! First of all, the location was superb – conference facilities, hotel, location. Come on – Barry Manillow and the Star Trek Experience? Geek heaven. The weather was fantastic (although a bit warm during the day), and having the monorail to travel to/from the Strip was convenient.

The exhibits were also good (as usual). There seemed to be quite a few of the process-oriented vendors this year – a good thing, if you ask me. And, let's face it, the giveaways and gadgets were spectacular. The food was also great. Personally, I think that the speakers were better than ever this year. It was good seeing a lot of old friends, and making new ones. The only drawback was that with all of the distractions, far too many of us stayed up late, and made the 2008 SSTC conference a conference to remember. What more could you ask for?

Except that I am writing this column in March, and the SSTC conference is still a month in the future. However, I am totally convinced that almost everything I wrote above will be true, and that after the conference ends, I will be able to argue that I was very successful in predicting the future. If only software were so easy.

The theme of this issue is Software Quality. I have a very unique definition of quality. In my mind, quality was defined by Simon and Garfunkel back in 1970 on their “Bridge Over Troubled Water” album (arguably the best piece of music ever released). There was a song entitled “Keep the Customer Satisfied.” Awesome lyrics. And that is the key – keeping the customer satisfied.

So, how do I achieve this dubious thing called quality which is hard to measure directly? Well, I am sure that this issue contains great articles about quality (since I’m writing in the future, I don’t even know the article lineup yet!).

In my mind, quality needs to include customer satisfaction. Is the software going to be used in a passenger aircraft? Well then, as a potential customer, I am pretty darn hard to satisfy. The other day, I was flying “across the little pond” (returning from London across the Atlantic) and the in-seat entertainment system I was using crashed – I actually got a core dump error message and saw Linux rebooting. The lady sitting next to me had it happen to her, and her comment was, “I sure hope that the software that runs the aircraft works better.” Well, having worked with several aircraft software developers, I can assure you that it does run much better. Is the software going to be used to simply rip a few of my old CDs to MP3s so that I can load them onto my latest gadget? Then I am willing to have it occasionally fail. I have a feeling that the latest SuperX MP3 Ripper program I downloaded free off the Web cost a lot less per line of code to develop than the software that will power the Joint Strike Fighter.

Which brings me back to forecasting the future. Forecasting the future is not an exact science. A friend of mine who is a meteorologist says that an 85 percent to 90 percent success rate in intermediate range predictions (one to three days out) is great. Two weeks out? More general predictions (i.e., warming trend) give the forecaster some leeway. One day out? A high of 73 with afternoon showers, ending by 9 p.m. tonight.

The secret to quality is the same: if you really think you can set a schedule (such as 28 lines of code per programmer per day) that will allow your developers to achieve a quality target (“No more than two errors found per 500 function points during integration testing”) that is also reasonably accurate one year out, well ... how did you enjoy SSTC 2009? Even with lots of historic data for similar projects, each development effort is different. Weather forecasters have access to about a hundred years of hurricane data, but still cannot tell me one month out when and where (or even if) a hurricane is going to hit the United States.

Quality is fragile. It is hard to achieve and, once lost, it seems to be gone forever. You can't test quality back in – those who have tried know better. You have to plan aggressively for quality and you have to have a good process for it (I wasn’t kidding earlier – the more process-oriented vendors at SSTC, the better it is for Department of Defense software in general).

Forecast the future as best you can. Revise your forecasts (and timelines) as you get closer to your goals. A good weather person has no problem saying, “Well, last week we said generally clear, but prepare for a heavy rain tomorrow.”

A good program manager might just have to say, “We had hoped to be in integration testing this week, but we need another month to complete inspections and peer reviews.” Nobody wants to hear that their vacation and beach plans are going to be washed away, but it happens. Nobody wants to hear that we are having problems with code quality, but if you have a good forecast and update it as needed, maybe you won’t.

Hope you enjoyed SSTC 2008 – and see you at SSTC 2009. Trust me – it was great, also!

Can You BACKTALK?

Here is your chance to make your point, even if it is a bit tongue-in-cheek, without your boss censoring your writing. In addition to accepting articles that relate to software engineering for publication in CROSSTalk, we also accept articles for the BACKTALK column. BACKTALK articles should provide a concise, clever, humorous, and insightful perspective on the software engineering profession or industry or a portion of it. Your BACKTALK article should be entertaining and clever or original in concept, design, or delivery. The length should not exceed 750 words.

For a complete author's packet detailing how to submit your BACKTALK article, visit our Web site at <www.stsc.hill.af.mil>.
Software Assurance Program

Software is essential to enabling the nation’s critical infrastructure. To ensure the integrity of that infrastructure, the software that controls and operates it must be reliable and secure.

Visit https://www.us-cert.gov/SwA to learn more about the software assurance program and how you can become more involved.

Security must be “built in” and supported throughout the lifecycle.

Visit https://BuildSecurityIn.us-cert.gov to learn more about the practices for developing and delivering software to provide the requisite assurance.

Sign up to become a free subscriber and receive notices of updates.
